Abstract

More than 50% of water supplies in the conterminous United States originate on forestland or rangeland, and are potentially under increasing stress as a result of larger and more severe wildfires. Little is known however about the long-term impacts of fire on annual water yield, and the role of climate variability within this context. We here propose a framework for evaluating wildland fire impacts on streamflow that combines double-mass analysis with new methods (change point analysis, climate elasticity modeling, and process-based modeling) to distinguish between multi-year fire and climate impacts. The framework captures a wide range of fire types, watersheds characteristics and climate conditions using streamflow data, as opposed to other approaches requiring paired watersheds. The process is illustrated with three case studies. A watershed in Arizona experienced a +266\% increase in annual water yield in the 5 years after a wildfire, where +219\% was attributed to wildfire and +24\% to precipitation trends. In contrast, a California watershed had a lower (-64\%) post-fire net water yield, comprised of enhanced flow (+38\%) attributed to wildfire offset (-102\%) by lower precipitation in the post-fire period. Changes in streamflow within a watershed in South Carolina had no apparent link to periods of prescribed burning but matched a very wet winter and reports of storm damage. The presented framework is unique in its ability to detect and quantify fire or other disturbances, even if the date or nature of the disturbance event is uncertain, and regardless of precipitation trends.
INTRODUCTION

Concerns about wildfire impacts on water supply have grown in recent years as a result of longer wildfire seasons and increasing annual area burned (Neary et al., 2005; Bladon et al., 2014). Reliable water supply is a critical ecosystem service of forests and rangelands, where more than 50% of freshwater supply in the conterminous United States originates (Brown et al., 2008; Sun et al., 2015a). In these areas, fire impacts on peak flows, base flows and annual water yields can last for years and potentially affect downstream municipal water supplies (Shakesby and Doerr, 2006; Silins et al., 2014), and this is a critical issue given the increasing demand for water. Wildfire can disrupt the hydrologic cycle in several ways. The formation of an ash layer or hydrophobic layer may inhibit infiltration and reduce lateral flow in the soil (DeBano, 2000; Jung et al., 2009), while evapotranspiration (ET) can decline as a result of canopy loss. Canopy loss increases net precipitation at the surface (Helvey and Patric, 1965; National Research Council, 2008), leading to more surface runoff and accelerated storm flow. Examples are known in the western U.S. of increases in storm runoff between 9% and 88% (Jung et al., 2009), and annual yield increases in the first post-fire year between 50% and 200% (Helvey, 1980; Troendle and Bevenger, 1996; Bart et al., 2016), however these effects vary by geographic region and depend on pre-fire conditions, fire severity and post-fire climate (Neary et al., 2005). ET may decline for several months even after a low severity prescribed fire (Clark et al., 2012; Renninger et al., 2013), and given the importance of ET for the water balance (Sun et al., 2015a, b) this may alter streamflow response depending on local conditions. Yet in absence of any widely applicable approach to link streamflow variations to fire disturbance, impacts on streamflow remain largely unquantified across broad regions.

Paired watershed analysis has long been the standard for quantifying multi-year disturbance impacts (Bosh and Hewlett, 1982), however a lack of comparable conditions between watersheds often limits the analysis to local data. Double-mass analysis (Merriam, 1937; Searcy and Hardison, 1960) requires only local data and assumes an approximately linear relationship between for example precipitation and streamflow when there are no changes in climate, land cover or water withdrawals, and has been used to assess streamflow changes after fire (e.g. Anderson et al., 1955), forest harvesting, mountain pine beetle infestations (Wei and Zhang, 2010; Zhang and Wei, 2012), and urbanization (Hao et al., 2015). The assumption of linearity represents a limitation of double-mass analysis because when gradual disturbances overlap it is difficult to identify the undisturbed state of a system (Glenn-Lewin et al., 1992; Temperli et al., 2013). Time series analysis now features methods such as change point analysis (Hawkins et al., 2003; Hawkins and Zamba, 2005; Wang et al., 2016) to identify the timing of significant change in the location and scale of a time series rather than relying on a second variable like the double-mass analysis, and has been applied in various climate and hydrological studies (Yang et al., 2009; Huang et al., 2014; Matsuyama et al., 2002; Vivès and Jones, 2005; Caldwell et al., 2016). The simultaneous effect of climate variability on streamflow can be filtered with a climate elasticity model (CEM; Schaake, 1990; Sankarasubramanian et al., 2001) that expresses the rate of streamflow change as the rate of change of a set of climate parameters, such as precipitation and temperature (Fu et al., 2007) or precipitation and potential evapotranspiration (PET) (Hao et al., 2015). Biederman et al. (2015) found that the CEM with precipitation and temperature parameters was not a significantly better model than the CEM based on precipitation alone.

Despite the large number of studies conducted in California, the Southwestern United States, the Rocky Mountains and the Southeastern United States, current knowledge about fire impacts on annual water yields in the United States is fragmentary and based primarily on only a small number of experimental watersheds in the western states. The restricted set of fire properties, watershed characteristics and climate patterns in these watersheds limits the understanding of the broader range of possible relationships and effects, and the question then is (1) how to adequately combine
hydrological data and methods in order to detect impacts of local fires on water yields at the watershed scale, and (2) how to distinguish these fire impacts from the effects of other watershed disturbances.

Objectives and approach

The objective of this study was to develop and demonstrate a general framework for the assessment of wildland fire impacts (wildfire and prescribed fire) on watershed annual water yields by separating the effects of local fires from the effects of climate variability and other watershed disturbances. This framework responds to the need to incorporate wildland fire effects into the assessment of water supplies in order to adapt planning efforts to the resilience of local water supplies to fire impacts (Martin, 2016), and answers to calls for a useful tool of fire impact assessment in addition to existing pyrogeographic frameworks (Bowman et al., 2013; Krawchuk and Moritz, 2014). It relies only on local climate and streamflow data, using pre- and post-disturbance streamflow data as opposed to alternative approaches relying on watershed pairs, and combines the classical techniques of double-mass and flow duration analysis with recent techniques including change point analysis, climate elasticity modeling and process-based hydrological modeling. A non-exhaustive demonstration of this framework includes three case studies on watersheds in three different physiographical regions of the conterminous U.S., i.e. South Carolina (with annual prescribed burning), Arizona and California (both with wildfires). Special consideration was given to the South Carolina watershed, where we used the change point model to detect and characterize multiple types of disturbance in the streamflow data.

METHODS

Framework for evaluating wildland fire impacts on streamflow

The framework for evaluating the impacts of hydrologic disturbance in watersheds consists of five methods that address various aspects of hydrological changes and disturbances evaluated for a multi-year post-disturbance period with respect to a reference period.

1. Determining the timing of hydrologic disturbance with the change point model (CPM)
2. Double-mass analysis of streamflow and precipitation data (DMC)
3. Analysis of precipitation duration curves (PDC) and streamflow duration curves (FDC)
4. Attribution of changes in streamflow to climate variability and watershed disturbance using the climate elasticity model (CEM)
5. Comparison with attribution analysis obtained with results of the process-based Water Supply Stress Index model (WaSSI)

Timing the hydrologic disturbance with the change point model (CPM)

The change point model (CPM; Hawkins et al., 2003; Hawkins and Zamba, 2005) can detect change points in a continuous time series corresponding with an unidentified disturbance such as wildland fire. An undisturbed continuous time series of streamflow may be assumed to follow a single distribution \( F_0 \), however if a change point exists the time series will follow a distribution \( F_1 \) prior to the change point and a distribution \( F_2 \) after the change point, where \( F_1 \neq F_2 \). Consequently, we defined the null hypothesis for a streamflow series without change point as (after Hawkins and Zamba, 2005; Ross, 2015):

\[
H_0 : Q_i \sim F_0(Q; \theta_0) \quad i = 1, 2, ..., T
\]
where discharge $Q$ at any given moment $i$ follows one single distribution $F_0$, which is a function of $Q$ and a set of parameters $\theta_0$. The alternative hypothesis was defined as:

$$H_1 : Q_i \sim \begin{cases} F_1(Q; \theta_1) & i = 1, 2, \ldots, \tau \\ F_2(Q; \theta_2) & i = \tau + 1, \tau + 2, \ldots, T \end{cases}$$

(2)

where $Q_i$ follows distribution $F_1$ defined by parameter set $\theta_1$ prior to change point $\tau$, and distribution $F_2$ afterwards with a different set of parameters $\theta_2$.

The null hypothesis was tested by running through the entire time series and calculating the non-parametric two-sample Lepage ($L$) statistic at each time step and evaluating the differences between the parts of the time series before and after every potential $\tau$. Lepage combines the Mann-Whitney (or Wilcoxon rank-sum, denoted $U$) statistic for detecting location shifts with the Mood statistic for detecting scale (dispersion) shifts (denoted $M$, Lepage, 1971):

$$L = U^2 + M^2$$

(3)

Refer to the Appendix for the formulations of $U$ and $M$. A change in streamflow was detected when $L$ exceeded a critical value $h_\alpha$ corresponding with a given significance level ($\alpha=0.05$) total sample size $n$. Lepage-type tests do not require any knowledge of the underlying distribution of observations, and provide greater statistical power than the Mann-Whitney, Chi-square and student’s t-test statistics (Hirakawa, 1974; Lloyd et al., 2014). Applications include the detection of abrupt changes in precipitation (Matsuyama et al., 2002; Vivès and Jones, 2005), sunshine rate (Inoue and Matsumoto, 2007), streamflow (Yang et al., 2009), and the evaluation of the impact of reservoirs (Huang et al., 2014). Calculations were performed using the $cpm$ software in R (Ross et al., 2012; Ross et al., 2015; R Core Team, 2014).

**Double-mass analysis of the precipitation-streamflow relationship (DMC)**

DMCs were calculated using the monthly PRISM precipitation and USGS streamflow data to confirm the existence of a breakpoint in the precipitation-streamflow relationship indicating a change in water yields. First, two linear models (the unrestricted models) were fitted to the reference and post-disturbance periods separately, and one linear model (the restricted model) was fitted to the pooled data for both periods. Subsequently, a Chow test was performed to evaluate the equality of model coefficients of the unrestricted models vs. the restricted model. Monthly data were used to allow a more precise separation of reference and post-disturbance data, which was necessary given a variable seasonal timing of disturbance events in different watersheds. See Appendix for equations.

**Characterization of changes in precipitation duration and flow duration (PDC and FDC)**

In order to characterize and visualize changes in the time distribution of precipitation and streamflow between the reference and post-disturbance period, we calculated the reference and post-disturbance PDCs and FDCs for each watershed according to the flow duration principle (Foster, 1934; Vogel and Fennessey, 1994; see Appendix). Precipitation duration curves were calculated from Daymet precipitation aggregated to the watershed scale, and flow duration curves were calculated from the USGS GAGES-II daily streamflow data. We then identified changes in the number of precipitation days (or “rain” days) $>$1 mm and the number of extreme precipitation days with $\geq$50.8 mm (Karl et al., 1995).
Attribution of changes in streamflow to climate variability and watershed disturbance using the climate elasticity model (CEM)

The climate elasticity model (CEM) was used to identify the portion of change in mean annual streamflow attributed to climate variability as opposed to the change caused by a disturbance. We calculated for each watershed a reduced one-parameter model (CEM₀) and a two-parameter model (CEM₁). The one-parameter model was formulated as (Schaake, 1990; Sankarasubramaniam et al., 2001):

\[
\text{CEM}_0: \quad \frac{dQ}{Q_0} = \alpha \frac{dP}{P_0}
\]

(4)

and the two-parameter model as:

\[
\text{CEM}_1: \quad \frac{dQ}{Q_0} = \alpha \frac{dP}{P_0} + \beta \frac{dPET}{PET_0}
\]

(5)

where the change in mean annual streamflow as a fraction of mean annual streamflow during the reference period \(dQ/Q_0\) is a linear function of the relative changes in mean annual precipitation \(dP/P_0\) and potential evapotranspiration \(dPET/PET_0\). Parameters \(\alpha\) and \(\beta\) were fitted to the data of the reference (pre-disturbance) period.

In order to derive the contribution of watershed disturbance, or more specifically fire disturbance in the case of the AZ and CA watersheds, we assume that the observed change in streamflow \((\Delta Q)\) is comprised of a climate induced change \((\Delta Q_{clim})\) and a component attributed to the hydrologic disturbance \((\Delta Q_{dist})\) (Wei et al., 2010; Hao et al., 2015):

\[
\Delta Q = \Delta Q_{clim} + \Delta Q_{dist}
\]

(6)

Next, the one and two-parameter CEMs of change in streamflow were evaluated with the corrected (small sample) Akaike’s information criterion (AICₖ) (Sugiura, 1978; Hurvich and Tsai, 1991; definition given in the Appendix).

Process-based attribution of streamflow changes with the Water Supply Stress Index model (WaSSI)

The process-based Water Supply Stress Index (WaSSI) was calculated to corroborate the results of the attribution analysis obtained with the empirical CEM. WaSSI (Sun et al., 2008; 2011) has been used in CONUS-wide studies for example to evaluate environmental change impacts on ecosystem services (Caldwell et al., 2011), effects of urbanization and water withdrawals on streamflow (Caldwell et al., 2012), impacts of dairy production on water scarcity (Matlock et al., 2013) and drought effects in national forests (Sun et al., 2015a). Monthly precipitation and air temperature from gridded PRISM data were scaled to the 12-digit HUC watershed scale, and used as input for WaSSI to calculate monthly water balances for eight land cover classes for the reference and post-disturbance period. Water yield simulations in WaSSI provided a baseline accounting for climate variability, and a comparison with observed streamflow allowed us to estimate the non-climate or disturbance contribution as a function of time (Eq. 6). A difference with the CEM approach is that this method uses monthly time intervals instead of the reference and post-disturbance period totals. Processes simulated in WaSSI include infiltration, ET, surface runoff, snow accumulation and snow melt, soil water storage and streamflow. Infiltration, soil storage and surface runoff were computed with algorithms from the Sacramento Soil Moisture Accounting Model (SAC-SMA; Burnash et al., 1973; Burnash, 1995) with input from the State Soil Geographic Database (STATSGO; Natural Resources Conservation Service, 2012) and 2005 domestic water usage data (USGS; Kenny et al., 2012). A

complete description of the WaSSI model can be found in Sun et al. (2008, 2011) and Caldwell et al. (2012).

Navigating the framework

The methods described above were integrated into one framework for evaluating the impacts of hydrologic disturbance in watersheds (Figure 1). There are multiple routes to navigate the framework, depending on available data and the nature of these data for a given watershed. For watersheds with a single fire disturbance in the evaluated period, the ignition date (if known) can be used to separate the reference and post-disturbance periods and no CPM is needed. The procedure for watersheds with multiple disturbances of any type (wildfire, active prescribed burning policy, logging operations, storm damage, construction, water management or water use) relies on a CPM of the streamflow time series to find the timing of the disturbance event(s) with the greatest hydrologic impact. A single abrupt change in streamflow over a given period of time will yield a single significant maximum value $L_{\max}$ in which case the corresponding time separates the reference and post-disturbance periods. Conversely, if there is no significant $L_{\max}$ there is no significant change in streamflow. Regardless, streamflow may exceed the discharge predicted based on precipitation, which can be tested using the Chow test of differences in the double mass relationship between multi-year streamflow and precipitation. If the corresponding F statistic is not significant, the post-disturbance change in streamflow is minor or short-lasting with regard to the length of the evaluated period, in which case the attribution analysis is not meaningful. Conversely, if the corresponding F statistic is significant there is likely a non-climate contribution to changes in streamflow, which can be calculated with the CEM and corroborated with results from the WaSSI simulation. The PDC and FDC help to characterize changes in extreme precipitation and streamflow that may contribute to long-term changes in water supply. The normal calendar year is used for the analyses based on annual data, with the year in which the disturbance occurred included in the post-disturbance period.

Datasets

Streamflow data

An overview of all used datasets is given in Table 1. Daily streamflow data were retrieved for the flow stations 2130900 (SC), 9508300 (AZ) and 11274630 (CA) and after extracting the data for selected watersheds, daily values were aggregated to monthly and annual watershed yield. Watershed boundaries were determined using the GMTED2010 elevation model (236 x 236 m resolution).

Climate data

Monthly climate precipitation was obtained from the PRISM (Parameter-elevation Regressions on Independent Slopes Model) gridded dataset (Spatial Climate Analysis Service, 2004) and scaled to the watersheds for the purpose of subsequent analysis in the change point analysis, double-mass analysis, attribution analysis and hydrologic simulations. Daily precipitation was extracted from the gridded Daymet dataset (Thornton et al., 2014) and scaled for the precipitation and flow duration analysis. Monthly PET was calculated using Hamon’s method as a function of monthly aggregated (mean) air temperature and day length (Hamon, 1961; Sun et al., 2011).

Fire data and vegetation index

The Monitoring Trends in Burn Severity dataset (MTBS; Eidenshink et al., 2007) integrates fire data from across the conterminous U.S. from 1984 to present. MTBS characterizes burn severity (30 x 30 m cells) of an area within fire perimeters based on the differenced normalized burn ratio (dNBR; Key and Benson, 2006) and the relative differenced normalized burn ratio (RdNBR; Miller and Thode, 2007), which are calculated from Landsat Thematic Mapper (TM) and Enhanced Thematic Mapper (ETM+) images using the reflectance in near-infrared (Landsat band 4) and mid-infrared (Landsat
band 4) recorded before and after a fire. These data have been used to analyze wildfire trends (Dennison et al., 2014) and forest disturbance (Hart et al., 2015) among others. MTBS data were used to characterize the burn severity within the watersheds, after which we determined the temporal evolution of MODIS normalized difference vegetation index (NDVI) for each burn severity class in percentage.

**Study watersheds**

We selected three burned watersheds in different regions of the conterminous United States (CONUS), each with a significant burned area to drainage area ratio (>5%) and a minimum drainage area of 25 km², to demonstrate the proposed framework (Figure 2, Table 2).

**Black Creek watershed, South Carolina with prescribed burning (34.51°N, 80.18°W)**

The Black Creek watershed (henceforward referred to as the SC watershed) is part of the greater Lower Pee Dee subbasin and the largest of the three watersheds by area (295.4 km²). It also has the lowest altitude (79-219 m) and mean gradient (2.5%), and consists of grassland (21%), evergreen forest (33%, mostly longleaf pine) and deciduous forest (10%) (Figure 3a). Woody wetlands are found along the Black Creek and its tributaries. The 30-year average precipitation (1981-2010) was 1144 mm and PET was 981 mm. Climate was characterized as temperate without dry season and with hot summers, or Cfa (1961-1990 and 1951-2000; Godfrey, 1999; Kottek et al., 2006). Annual prescribed burning has been conducted in the Carolina Sandhills National Wildlife Refuge (NWR) in the lower portion of this mixed land use watershed since at least the 1940s, and 40% of the watershed was burned between 2004 and 2014 (Figure 3a). Burn severity was typically low. Fire impact on the interannual variability of vegetative phenology evidenced by the NDVI was limited, with seasonal NDVI values peaking between 73% and 74% and minimum values between 54% and 57% (Figure 4a).

**Wet Bottom Creek watershed, Arizona and 2004 Willow wildfire (34.16°N, 111.69°W)**

The Wet Bottom Creek watershed (or AZ watershed) drains 93.0 km² and has the greatest variations in terrain of the three watersheds, with slopes ranging between 0.1% and 76.1%. The upper parts with an altitude up to 2157 m received snowfall during some winters and were covered with evergreen forest (57%) of pinyon juniper and ponderosa pine (Figure 3b). These upper parts drain through a narrow rocky valley vegetated with shrubs (43%, mostly chaparral). The climate is temperate with dry and hot summers (Csa; Godfrey 1999) with an annual precipitation of 473 mm, however the lower part in the western extremity of the watershed is drier. The average PET of 873 mm exceeded precipitation. The Wet Bottom Creek is a tributary of the Verde River, one of the last free-flowing perennial rivers in Arizona. Groundwater pumping in parts of the Verde River basin has raised concern about the effects on riparian vegetation (Leake and Pool, 2010). The Willow wildfire that started on June 24th, 2004 affected 83.6% of the watershed, with under/unburned to low burn severity (10.7% and 46.3%, respectively, of the watershed) on the more sparsely vegetated south-facing slopes, and moderate burn severity (26.2% of the watershed) on the north-facing slopes (Figure 3b). Approximately 0.5% of the watershed was affected by high severity burning. Fire reduced NDVI from approximately 0.60 to 0.26 (moderate and high burn severity) and from 0.41 to 0.29 (low burn severity). After two years, NDVI showed signs of initial recovery in the severely affected evergreen forest (Figure 4b) and in 2014, ten years after the fire, summer peak NDVI was 0.48 and demonstrated progress in post-disturbance recovery despite a low precipitation of <400 mm in 2006, 2009, 2011 and 2012.

**Del Puerto Creek watershed, California and 2003 Deer Park wildfire (37.48°N, 121.20°W)**

The Del Puerto Creek watershed (hereafter CA) spans 187.4 km² and drains into the agricultural Central Valley. Average annual precipitation was a mere 418 mm and PET was 904 mm. The upper
part of the CA watershed consisted of scrubland/shrubland with sagebrush and chaparral (57% of the watershed) (Figure 3c). Overall, the CA watershed had the lowest forest cover of the three watersheds. Before disturbance, the east-facing headwater slopes had a mixed forest cover (14%, canopy cover 25-50%) with pine oak and eucalyptus, and the lower eastern part of the watershed was mostly grassland (28%). The Deer Park wildfire started on July 20, 2003 on a hillslope in the upper part of the watershed and burned 14.1% of its area (Figure 3c), with moderate to high burn severity (3.8% and 1.2%, respectively, of the watershed) on the chaparral covered hillslopes, and unburned/underburned to low burn severity near streams (4.9% and 4.1%, respectively). The NDVI in the severely burned area decreased (Figure 4c) from around 0.58 during the summer peak to around 0.30 in autumn. Areas categorized as unburned to underburned likewise decreased in NDVI during the same period, from approximately 0.55 to 0.33.

**RESULTS**

We identified the 5 year reference (pre-disturbance) and 5 year post-disturbance periods immediately preceding and following the wildfire starting dates reported in the MTBS dataset for the AZ and CA watersheds, respectively. Due to the large number of prescribed fires reported for the SC watershed (44 between 1984 and 2013; MTBS) we here used the change point model to identify the most significant disturbance in the streamflow data for the period overlapping with the MTBS and PRISM datasets (1984-2012). The remainder of the analysis was performed according to the framework and included the evaluation of DMC, PDCs and FDCs (discussed in the Appendix), CEMs and WaSSI hydrologic simulations. Evaluated periods follow the calendar year, chosen as a trade-off between the hydrologic year, often starting on October 1st in the conterminous U.S., and the fire season, which can start as early as March or April. The AZ watershed had the greatest increase in 5 year post-wildfire annual water yield (+266%) while the SC and CA watersheds had a lower post-wildfire annual water yield (-39% and -64%, respectively).

**South Carolina watershed**

**Change point analysis of streamflow data**

Critical value $h_n$ was exceeded in the years 1998 through 2000 using an annual time step (Figure 5a). Greater statistical power was obtained at a monthly time step (Figure 5b), which also allowed us to select the month with the greatest $L$ (May 1999) as the disturbance change point to be evaluated.

**Double-mass curves**

The disturbance of May 1999 also represents a break point in the relationship between cumulative streamflow and precipitation ($p<10^{-6}$) (Figure 6a), with the coefficient of the unrestricted linear model (runoff coefficient) declining from 0.419 (5 year reference) to 0.306 in the post-disturbance period. The corresponding residual plot offers a more detailed view of the seasonal oscillations representing the time lag between cumulative precipitation and runoff caused by higher runoff in the winter, when soils are wetter than in the summer. Even compared to the 10 year reference period the change in runoff is still significant ($p<10^{-6}$).

**Attribution of streamflow change (climate elasticity model)**

The one-parameter (precipitation) CEM$_0$ was retained at the expense of the two-parameter (precipitation and PET) CEM$_1$ for all three watersheds and evaluated periods (Table 3), based on a higher AIC$_c$ value. Each CEM$_0$ with a positive fitted value of $\beta$ was rejected because this wrongly implies a scenario where a higher PET leads to more streamflow. The 5 year CEM$_0$ predicted a -242 mm (-47%) change in annual streamflow vs. a -201 mm (-39%) observed change (Table 3 and Figure.

This article is protected by copyright. All rights reserved.
The difference between observed change in streamflow $\Delta Q_0$ and the contribution of climate $\Delta Q_{\text{clim}}$ predicted by the CEM amounts to +42 mm (+8%) unaccounted for by climate, and is subsequently assumed to represent the net positive contribution of watershed disturbance $\Delta Q_{\text{dist}}$. The decrease in annual streamflow was -178 mm (-36%) relative to the 10 year reference period vs. 201 mm (-39%) relative to the 5 year reference period, and lower precipitation was the dominant factor in both cases (Table 3 and Figure 7).

**WaSSI hydrologic simulation**

The WaSSI simulated streamflow (Figure 8a) confirmed the declining trend in streamflow found in the attribution analysis. The found date of April 1998 corroborates with the significant time interval found in the change point analysis.

**Arizona watershed**

**Double-mass curves**

Values of the F statistic were comparable to the SC values ($p<10^{-6}$), however here the linear model coefficient (runoff coefficient) increased considerably, from 0.132 (5 year reference period) to 0.393 (Figure 6b), in response to the exceptionally wet period between November 2004 and February 2005 (80 mm to 165 mm per month). The increase in runoff coefficient with respect to the 10 year reference period was in the same order of magnitude. The effect of the wildfire was observed during the first winter, where the residual plot shows that runoff is nearly 400 mm more than expected. The runoff coefficient had not recovered to its pre-disturbance value 5 years after the fire in 2009, based on the increasing trend in the residual plot (Figure 6b), nor even as late as 2012 verified with additional analysis.

**Attribution of streamflow changes (climate elasticity model)**

The 5 year CEM$_0$ predicted an increase in streamflow of 24 mm (+47%) corresponding to an increase of precipitation from 437 mm to 507 mm. This predicted increase in streamflow fell short of the observed increase of +134 mm (+266%), with the difference (+110 mm or +219%) representing the effect of the 2004 Willow Fire in this watershed. Although fire disturbance is responsible for a considerable increase in runoff, the effect was amplified by increased precipitation (Table 3 and Figure 7a). Although the change in streamflow was much smaller evaluated over a longer period, relative contributions (Table 3 and Figure 7b) of climate and fire disturbance were proportional to the changes observed relative to the 5 year reference period.

**WaSSI hydrologic simulation**

The residual plot in Figure 8b (right panel) shows that the hydrological model reproduced the observed values correctly until the autumn of 2000, but was unable to simulate the intermittent character of streamflow after this date. While the dry winters were simulated correctly, the discrepancy was possibly related to low winter precipitation in 2003 and 2008, which represented a greater challenge for calculating water balances and lead to an overestimation of the non-climate contribution to streamflow changes (Figure 8b right panel). Nonetheless, the model simulated the dynamic of rapid increase in streamflow in November-December 2004 following the wildfire while the observed streamflow increased even more rapidly than before, providing minimal additional evidence of a non-climate contribution to streamflow change.
Double-mass curves

There was a significant breakpoint in the DMC corresponding with the July 2003 Deer Park wildfire ($p < 10^{-6}$), and runoff coefficient increased from 0.04 (4%) to 0.058 (5.8%) (Figure 6c, left panel). Unlike the AZ watershed this increase was not observed until the second winter after the fire, in December 2004. The DMC for the 10 year reference period (Figure 6c, right panel) shows that there is a moment of even greater change in the DMC corresponding with the exceptionally high rainfall of 158 mm and 251 mm in January and February 1998, respectively.

Attribution of streamflow changes (climate elasticity model)

Lower precipitation in the post-disturbance period (342 mm against 453 mm in the reference period) resulted in -33 mm (-64%) less streamflow. Judging from these numbers it would be difficult to argue that the 2003 Deer Park Fire could lead to more runoff, however CEM predicted a much greater reduction of streamflow (-52 mm or -102%) than observed, meaning that fire disturbance itself increased the streamflow by +19 mm (+38%). The disturbance partly offset the effect of a declining annual precipitation on annual streamflow relative to the 5 year reference period (Figure 7a). When evaluated for the 10 year reference period, the CEM fitted to this period could explain all of the change in streamflow.

WaSSI hydrologic simulation

The WaSSI simulation for this watershed was complicated by the systematic overestimation of summer and winter runoff, resulting in a propagated error in cumulative water yield (Figure 8c, center panel). Therefore the WaSSI results for the CA watershed could not be interpreted for the purpose of disturbance analysis.

**DISCUSSION**

The framework combines hydrological data and methods into a single procedure for the assessment of wildland fire impacts on water yields in single watersheds, and as such presents a more practical assessment tool compared to traditional paired watershed analysis.

**Can the framework quantify wildland fire impacts on streamflow?**

Yes, the framework uses CPM and DMC to detect changes in streamflow, and subsequently a CEM to distinguish between the respective contributions of climate and wildland fire or other non-climate related disturbances to that streamflow change. CEM results can subsequently be compared to an attribution analysis based on WaSSI hydrologic simulations. If other non-climate disturbances occurred than wildland fire alone, it is possible to estimate the relative impact of these disturbances using the CPM. As demonstrated for the three case studies, the contribution of fire disturbance to streamflow change can vary from negligible (SC) to substantial (AZ) or somewhere in between (CA).

Wildfire had an increasing effect on 5-year water yields in the AZ and CA watersheds, however the net amount of change in streamflow and the direction of this change also depended on climate trends: an amplified response in conjunction with a positive trend in precipitation in the AZ watershed and an attenuated response in the CA watershed where post-wildfire precipitation was lower. The framework found an increase in runoff coefficient of the CA watershed from 4% to 5.8% despite a -64% lower yield agrees with the steady baseflow observed throughout most of the winter in the post-fire period. The modest contribution of wildfire to streamflow change in the CA watershed was furthermore...
consistent with the rapid recovery of NDVI and conversely, the slow recovery of NDVI in the AZ watershed agreed with the large contribution of wildfire to streamflow change there.

The CEM associated streamflow changes in the SC watershed mainly to climate rather than to fire. Climate was quite variable with a wet winter in 1998 (September 1997 to April 1998 were all months with >100 mm) followed by a period of less precipitation and lower mean annual number of extreme precipitation days >50.8 mm (see Appendix). The change point model linked the time of maximum streamflow disturbance ($t_{max}$) to May 1999, where the CEM attributed the observed loss in water yield of -39% to a negative (-47%) climate contribution attenuated by a positive (+8%) non-climate contribution (5 year reference period). The change point analysis furthermore detected significant change in streamflow for the extended period between 1998 and 2000 (annual time step; Figure 5a) and 1995-2011 (monthly time step; Figure 5b), corresponding with periods of increased interannual and monthly variability in streamflow, respectively.

Although the framework was designed to quantify effects of climate trends and wildfire disturbance, other types of disturbance can also be identified when the approximate dates of disturbance found by the CPM can be linked to known events. The modest increase in streamflow in the SC watershed attributed to non-climate factors could not be linked with individual prescribed fires, which agrees with earlier observations by Troendle et al. (2010) that low severity prescribed fires are unlikely to influence water yield, especially compared to the effects of high severity wildfires. Estimates say that at least 20% of basal area of vegetation must be removed to cause any significant change in streamflow (Bosch and Hewlett, 1982; Stednick, 1996). Prescribed burnings followed a regular pattern (small fires with low burn severity; Carolina Sandhills NWR, 1998; 1999), no wildfires were reported, and bark beetle activity was very low (Carolina Sandhills NWR, 1998; 1999; South Carolina Forestry Commission, 1999). Therefore, the change in streamflow was possibly the result of a combination of dam failure (Carolina Sandhills NWR, 1994; 1999), beaver activity (Carolina Sandhills NWR, 1999), major weather events (severe thunderstorm on May 6th, 1999 that killed many trees; National Climatic Data Center Storm Events Database, retrieved February 8, 2016; and an ice and snowstorm on January 24-25, 2000; Carolina Sandhills NWR, 2000), or (unverified) water management and water usage.

**Does the framework account for overlapping watershed disturbances?**

The framework can separate climate effects overlapping with non-climate effects, however multiple overlapping non-climate disturbances are sometimes difficult to disentangle. This is the case for the CA watershed where there the DMC has no clear breakpoint for the 2006 Canyon Fire even though it burned an area similar in size to the 2003 Del Puerto Creek Fire. Hydrologic response to overlapping watershed disturbances are furthermore complicated by the interaction with extreme climate events and the gradual recovery of vegetation and evapotranspiration. Also, not all breakpoints in the DMC correspond with no-climate disturbance. For example, the 10-year reference period preceding the 2003 wildfire in the CA watershed includes both the strong El Niño year 1997-1998 with exceptionally high rainfall and the drier La Niña years 1998-1999 and 1999-2000, where the 5-year reference period included only the La Niña years. El Niño effects are strong in this part of California (Hoell et al., 2016), and the high precipitation during 1997-1998 phase may have resulted in erosion and alteration of the streambed, causing a breakpoint in the DMC (Figure 6c).

With a larger sample size and wider range of annual precipitation and runoff, a 10-year reference period will generally provide more robust estimates of CEM coefficients than the a 5-year reference period (see also Figure 4c). Nevertheless, this does not imply that the 10-year CEM improves the accuracy of the attribution analysis for individual wildfires because in the case of the CA watershed there was another, smaller fire (1996) in this period. The length of the evaluated reference and post-disturbance periods is a trade-off between the amount of hydrological data needed to construct a CEM on one hand and the likelihood of overlapping disturbance effects on the other hand. Choosing an appropriate length is very challenging in California watersheds where high fire frequency meets
extreme climate and ephemeral runoff, and in this case the true wildfire effect on runoff may lie
somewhere between the values attributed using the 5-year and 10-year reference periods, respectively.
It will be useful to evaluate whether the inclusion of antecedent climate conditions (temperature days,
precipitation, snow water equivalents) and monthly variance of high resolution precipitation data (Hao
et al., 2015) improves the CEM. Linking hydrologic disturbance directly to burn severity or MODIS
NDVI may also help validate the attribution analysis, although the more complex disturbance patterns
may necessitate a distributed ecological-hydrological model.

**Which climates work best with the framework?**

The accuracy of the attribution analysis depends on the performance of models in the framework, and
may be considered acceptable for temperate, humid and Mediterranean climates provided that annual
water yield efficiencies (runoff coefficients) are approximately constant during the pre-disturbance
and post-disturbance periods, respectively. The precipitation-only based CEMs with the best
performance in terms of AICc (low value reflecting the greatest maximum likelihood for n
observations) were obtained for the SC watershed (Table 3), with values of AICc = 6.16 (5 year
reference) and AICc = -2.45 (10 year reference). This is explained by the stable annual water yield (of
33%) and perennial streamflow resulting from year-round precipitation, which can be accurately
represented in a linear CEM. CEM performance for the AZ and CA watersheds was lower (greater
AICc values) because of a greater seasonal and interannual variability in the precipitation-streamflow
relationship associated with snowmelt (AZ) and El Niño effects (CA). Notwithstanding, snow is the
dominant hydrologic input in much of the western United States (Rocky Mountains, Sierra Nevada,
Cascade Ranges) and therefore snow processes (annual snowfall, snowmelt, sublimation) are
important controlling factors of streamflow disturbance in this area (Troendle and King, 1985;
Harpold et al., 2014). Long and short term drought is common in regions like Southern California,
Nevada and other parts of the Southwest, where it represents a contributing factor to wildfire and
affects streamflow (Littell et al., 2016). Hydrologic response to wildfire is highly non-linear in snow-
dominated, arid or drought-affected systems and under such conditions the framework would benefit
from a more physically based nonlinear CEM.

**What are some limitations of the framework?**

Other limitations are related to the way in which the attribution analysis identifies disturbance effects.
Fire impacts vary with burn severity, which affects the amount of leaf area reduction. High burn
severity reduces evapotranspiration drastically, increases net precipitation, and leaves the soil exposed
to direct rainfall impact (Winkler et al., 2010). Post-fire soil surface sealing and heat-induced soil
water repellency change the amount of runoff generated along the hillslope (Larsen et al., 2009; Ebel
etal., 2012), while the spatial sequence of burned areas controls how much of the generated runoff is
transported downhill (Moody et al., 2016). Storm flow studies emphasize the importance of the
organization of flow paths on the timing of flow delivery at the base of the hillslope (Hallema et al.,
2014; 2016) and the watershed (Hallema et al., 2013), however the framework lumps all these effects
together. This eliminates the possibility to evaluate wildland fire impacts on individual hydrological
processes (e.g., infiltration and storm flow generation) but also creates the possibility to evaluate
wildland fire effects on a much wider range of watersheds.
Why not use either CPM or DMC to evaluate disturbances instead of both?

The CPM and DMC were used to evaluate slightly different types of disturbances and are complementary tools in the framework. The CPM was used to detect observed changes in streamflow, while the DMC was used to evaluate changes in water yield efficiency (streamflow expected based on precipitation). This is necessary because wildfire and precipitation trends can partly cancel each other out (CA watershed) in which case streamflow data alone may not be sufficient to find the timing of the disturbance. On the other hand, CPM can detect multiple disturbances (with the Lepage test), where the classic DMC approach evaluates only one disturbance at a time (F test). Therefore the inclusion of both CPM and DMC offers the best chances of finding all significant disturbances. The disadvantage of CPM is that the Lepage statistic for intermittent or ephemeral streamflow series will rarely be significant \((L > h, \text{given } a)\) if there are many months out of the year with zero flow.

CONCLUSIONS

A framework was presented for the assessment of wildland fire impacts on annual water yields in watersheds. This framework uses a change point model to identify and assess multiple disturbances where existing, and a climate elasticity model to determine the contributions of climate variability and wildland fire to streamflow changes over a multi-year period. Case studies showed that the framework can detect delayed hydrological responses to wildfire, and establish whether wildfire enhanced or attenuated streamflow regardless of precipitation trends during the period of evaluation (AZ and CA watersheds). In the third case study (SC watershed) change in streamflow could not be linked to prescribed fire, but was chiefly attributed to a declining trend in precipitation.

Based on the outcomes we conclude that the framework has a potential to capture the streamflow impacts of wildfires, prescribed fires, and various other watershed disturbances under a variety of watershed characteristics (mountainous, mixed land cover) and climate conditions (humid and Mediterranean/temperate). The framework is a step up from traditional analyses because it can be used with long-term streamflow data from a single flow station, and does rely on paired watershed data. Furthermore, if there is more than one potential disturbance event, the change point model can indicate the relative impact of each disturbance, making the framework suitable for a wide range of applications including hydrologic impact assessment of wildland fires, erosion modeling and post-fire management. The challenge in the future development of the framework lies in the adaptation and proper representation of seasonal and interannual variability in the precipitation-streamflow relationship in the CEM for a wider range of conditions, including snowfall/snowmelt patterns, seasonal drought and multi-year drought.

ACKNOWLEDGMENT

The authors want to thank William M. Christie (USDA Forest Service) for processing NDVI and aerial detection survey data and John G. Cobb (USDA Forest Service) for his assistance with database development. We further acknowledge Dr. Danny C. Lee and the two anonymous reviewers, whose comments and suggestions have been extremely valuable in revising the manuscript. Financial support for this study was provided by the U.S. Department of Agriculture Forest Service Southern Research Station, the Joint Fire Science Program (project #14-1-06-18), and the U.S. Forest Service Research Participation Program administered by the Oak Ridge Institute for Science and Education through an interagency agreement between the U.S. Department of Energy and the USDA Forest Service. ORISE is managed by Oak Ridge Associated Universities (ORAU) under DOE contract number DE-AC05-06OR23100. All opinions expressed in this paper are the authors’ and do not necessarily reflect the policies and views of USDA, DOE, or ORAU/ORISE.

**APPENDIX**

**Methods and statistics**

**Mann-Whitney statistic**

The Mann-Whitney statistic is defined as (e.g. Yue et al., 2002; Ross et al., 2012):

\[
U = \min\{U_S, U_T\},
\]

\[
U_S = n_S n_T + \frac{n_S(n_S+1)}{2} - r(x_l)
\]

\[
U_T = n_S n_T + \frac{n_T(n_T+1)}{2} - r(x_l)
\]
where the subscripts $S$ and $T$ correspond to the sets of observations preceding and following the presumed change point $\tau$, respectively, $n$ is the corresponding number of observations, and $r(x_i)$ represents the pooled rank sums given all observations.

**Mood statistic**

The Mood statistic $M$ is given by (Mood, 1954; Ross et al., 2012):

$$M = \left| \frac{(M' - \mu_{M'})}{\sigma_{M'}} \right|$$

where

$$M' = \sum_{x_i \in S} (r(x_i) - (n + 1)/2)^2$$

$$\mu_{M'} = \frac{n_S(n^2-1)}{12}$$

$$\sigma_{M'}^2 = \frac{n_S(n^2(n+1)(n^2-4)}{180}$$

where $\mu_{M'}$ and $\sigma_{M'}^2$ are the mean and variance of the Mood statistic, respectively.

**Precipitation duration (PDC) and flow duration (FDC)**

The FDC is the complement of the cumulative distribution of streamflow that shows the percentage time a given streamflow was equaled or exceeded during the period of evaluation. This percentage represents the probability of exceedance $p$ of a given discharge $Q$, where $p$ is defined by (Foster, 1934; Vogel and Fennessey, 1994):

$$p = 1 - P\{Q \leq q\}$$

Each set of climate and watershed characteristics yields a unique FDC, and typically contains a fast flow component and a delayed flow component. The FDC changes as a result of climate variability and/or watershed characteristics, and for this reason provides an important indicator for watershed disturbance. The precipitation duration curve (PDF) was found by substituting streamflow in Eq. 7 with precipitation.

**Breakpoint detection in DMC with the Chow test**

The first step in detecting a breakpoint in the DMC was to calculate the cumulative streamflow and precipitation for the reference and post-disturbance cumulative data. Next, we determined the DMC by fitting two separate linear models (the unrestricted models) to the reference and post-disturbance periods, and estimated the cumulative runoff as follows:

$$Q_{cum,1} = a_1 + b_1 \cdot P_{cum,1} + \varepsilon_1$$

$$Q_{cum,2} = a_2 + b_2 \cdot P_{cum,2} + \varepsilon_2$$

This article is protected by copyright. All rights reserved.
where the subscripts \(1\) and \(2\) correspond with the reference and post-disturbance periods, respectively, and parameters \(a\) and \(b\) were fitted using the least squares method, and \(\epsilon\) represents the residual error. Note that in order to obtain a continuous unrestricted DMC, the linear model for the post-disturbance period was forced through the break point approximated by the model for the reference period.

The following step was to fit the restricted linear model to the pooled data for both periods. This restricted model was defined as:

\[
Q_{\text{cum},0} = a_0 + b_0 \cdot P_{\text{cum},0} + \epsilon_0
\]

(17)

If there is no breakpoint in the DMC it follows that:

\[
H_0: a_1 = a_2, b_1 = b_2
\]

(18)

This was evaluated by testing whether the differences in sums of squared residuals from the unrestricted model and the restricted model were statistically significant using the Chow test (Chow, 1960; Fisher, 1970).

The Chow statistic was calculated as (Chow, 1960; Fisher, 1970):

\[
F = \frac{\text{SSE}_0 - (\text{SSE}_1 + \text{SSE}_2)) / K}{(\text{SSE}_1 + \text{SSE}_2) / (n-2K)}
\]

(19)

with \(\text{SSE}_0\) the sum of squared errors for the restricted linear model representing the DMC for the pooled data, \(\text{SSE}_1\) and \(\text{SSE}_2\) the sum of squared errors for the unrestricted linear models for the reference and post-disturbance periods, respectively, \(K\) the number of regressors and \(n\) the number of samples.

**Corrected Akaike's information criterion**

The corrected (small sample) Akaike’s information criterion (AIC\(_c\)) was calculated as (Sugiura, 1978; Hurvich and Tsai, 1991):

\[
\text{AIC}_c = -2L_k + 2k + \frac{2k(k+1)}{n-k-1}
\]

(20)

where \(n\) is the number of observations, \(L_k\) is the maximized log-likelihood, and \(k\) the number of parameters in the climate elasticity model. The AIC\(_c\) is based on Akaike’s information criterion (Akaike, 1973), and imposes a greater penalty for extra parameters, thus decreasing the probability of overfitting the climate elasticity model as a result of adding too many parameters.

**Precipitation duration and flow duration curves**

**South Carolina watershed**

Mean annual precipitation in the SC watershed was lower in the post-disturbance period (Table 3) and the number of precipitation days \((p\{P_d \geq 1 \text{ mm}\})\) decreased from 113 to 101 days per year on average (exceedance \(p=0.31\) and \(p=0.28\), respectively; left panel in Figure 9a). Consequently, the 75\(^{th}\) percentile of daily flow \(Q_d\) decreased from 6.0 \(\text{m}^3\cdot\text{s}^{-1}\) to 3.6 \(\text{m}^3\cdot\text{s}^{-1}\) (Figure 9a, right panel). Mean annual number of extreme precipitation days \(>50.8 \text{ mm}\) also decreased, from 1.6 days \((p\{P_d \geq 50.8 \text{ mm}\})\) to 1.4 days \((p\{P_d \geq 50.8 \text{ mm}\})\) (Figure 9b).
mm} = 0.0044) to 0.6 days (p{P_d ≥ 50.8mm} = 0.0016), while the 10th percent discharge exceedance decreased from 9.1 m$^3$.s$^{-1}$ to 5.4 m$^3$.s$^{-1}$.

**Arizona watershed**

Precipitation in the AZ watershed increased from 437 mm to 507 mm in the post-disturbance period (Table 3), and the mean annual number of precipitation days likewise increased from 45 days (p{P_d ≥ 1 mm} = 0.122) to 49 days (p{P_d ≥ 1 mm} = 0.134; Figure 9b, left panel). Mean annual number of days with streamflow increased considerably from to 219 days (p{Q_d ≥ 1.0×10^{-3} m^3.s^{-1}} = 0.600) to 272 days (p{Q_d ≥ 1.0×10^{-3} m^3.s^{-1}} = 0.746), and the 10th percent discharge exceedance more than tripled (0.50 m$^3$.s$^{-1}$ vs. 0.15 m$^3$.s$^{-1}$) (Figure 9b, right). These high flows occurred mostly in the winter when the mean annual snow water equivalent varied between 8 mm (November) and 110 mm (January) (reference and post-disturbance period combined), and high daily maximum temperatures (12°C during the coldest month of January) allowed for immediate snowmelt.

**California watershed**

The CA watershed received less precipitation during the post-disturbance period, 342 mm compared to 453 mm in the reference period (Table 3). The mean annual number of precipitation days increased from 54 days (p{P_d ≥ 1 mm} = 0.158) in the reference period to 58 days (p{P_d ≥ 1 mm} = 0.148) in the post-disturbance period, while the number of days with moderate precipitation did not change substantially (1.2 days (p{P_d ≥ 25.4 mm} = 0.003) vs. 1.0 days (p{P_d ≥ 25.4 mm} = 0.0027), see Figure 9c, left). Heavy precipitation ≥50.8 mm was observed only once, during the reference period. Despite the minor change in precipitation duration and the 75th percentile of streamflow (from 7.4×10^{-2} m$^3$.s$^{-1}$ to ×10^{-2} m$^3$.s$^{-1}$ to 7.1×10^{-2} m$^3$.s$^{-1}$), flow variability increased substantially. The 10th percent discharge exceedance increased by +59% from 0.17 m$^3$.s$^{-1}$ to 0.27 m$^3$.s$^{-1}$ while the number of days with streamflow dropped from 275 days (p{Q_d ≥ 1.0×10^{-3} m^3.s^{-1}} = 0.616) to 172 days (p{Q_d ≥ 1.0×10^{-3} m^3.s^{-1}} = 0.472) (Figure 9c, right).

Table 3. Simulated contributions of climate change and (non-climate) watershed disturbance to changes in streamflow (mm.yr⁻¹) in the 5 years post-disturbance, including the year in which the disturbance occurred, vs. the 5 preceding years and 10 preceding years, respectively. Climate elasticity models of changes in streamflow include a reduced model based on changes in precipitation (CEM₀), and a two-parameter climate elasticity model based on changes in precipitation and PET (CEM₁). Model selection was based on the lowest small-sample AIC (Sugiura, 1978; Hurvich and Tsai, 1991).

Figure 1. Framework for evaluating wildland effects on streamflow.
Figure 2. Locations of the Black Creek (SC), Wet Bottom Creek (AZ) and Del Puerto Creek (CA) watersheds within the United States, and mean annual precipitation for the period 1981-2010 (PRISM).
Figure 3. 2001 Land cover (left panel) and burn severity (right panel) for the (a) Black Creek watershed (SC) with a series of 44 prescribed burns conducted between 2004 and 2013; (b) Wet Bottom Creek watershed (AZ) and the 2004 Willow Fire; and (c) Del Puerto Creek watershed (CA) and the 2003 Deer Park Fire (National Land Cover Database, 2011; Monitoring Trends in Burn Severity, 2014). Legends apply to all watersheds.
Figure 1. 1981-2010 normal annual precipitation (PRISM), observed streamflow (USGS), and bi-weekly normalized difference vegetation index (NDVI) for MTBS burn severity classes (1 - Under/unburned to low, 2 - Low, 3 - Moderate, 4 - High, 5 - Increased greenness) in the (a) Black Creek watershed (SC), (b) Wet Bottom Creek watershed (AZ) and (c) Del Puerto Creek (CA).
Figure 5. Change point analysis of the SC streamflow data for the period 1984-2012. Shown are the streamflow time series and Lepage test statistics evaluated for (a) annual time intervals and (b) monthly time intervals. The vertical dashed line indicates the estimated change point location corresponding with the greatest value of the Lepage statistic, and $h_n$ marks the statistic value for a significance level of $\alpha=0.05$. 
Figure 6. Double-mass and residual plots of monthly streamflow (USGS-GAGES-II) and monthly precipitation (PRISM) for the period that includes 5 years pre-disturbance and 5 years post-disturbance (left panel), and for the period that includes 10 years pre-disturbance and 5 years post-disturbance (right panel). The DMC based on the restricted linear model is represented by the orange dashed line, while the blue and red lines represent the DMC based on the unrestricted linear models fitted to the reference and post-disturbance periods, respectively. The residual plots show the residuals with respect to DMC fitted to the corresponding reference period.
Figure 7. Attribution of the mean change in annual streamflow to climate variability (precipitation) and (non-climate) watershed disturbance, given in % change in the 5 year post-disturbance (including the year in which the disturbance occurred), vs. the 5 preceding years (a) and 10 preceding years (b), respectively.
Figure 8. Cumulative contributions of climate variability on streamflow simulated in WaSSI and (non-climate) watershed disturbance calculated as the difference between observed and simulated cumulative streamflow.
Figure 9. Precipitation duration curves (PDCs) based on Daymet daily precipitation data aggregated to the watershed scale for the 5 year periods before (dashed) and after disturbance, and corresponding flow duration curves (FDC) based on daily USGS GAGES-II streamflow data.
