Abstract

Industrial forestry activities can increase landscape fragmentation, impacting wildlife populations, particularly Canada’s woodland caribou, Rangifer tarandus caribou. To protect caribou in areas with forestry activities, the province of Ontario, Canada, implemented a Dynamic Caribou Harvest Schedule (DCHS). The DCHS spatially aggregates harvest disturbance into regions and distributes them across the landscape to maintain forest patch size–age distributions consistent with a natural variation range. However, the DCHS may negatively impact the cost of timber supply. We compared the DCHS with an alternative zoning approach that assigned the harvest deferral and operational management zones within a large forest area. We compared these approaches using an optimization model that combined harvest scheduling, access road construction, and caribou protection sub-problems. We formulated the protection of caribou habitat and road construction as network flow problems, while the harvesting problem incorporated the ecological constraints prescribed by the forest management plan. We compared the DCHS and zoning approaches in the Wabadowgang Noopming Forest of Ontario, a boreal area within the caribou distribution zone. For the same volume of sustainable harvest, the zoning approach protected less total area but more habitat and old-growth stands over the long term, and yielded lower timber costs by 1.2–2.2 $·m⁻³ than the DCHS.

Key words: dynamic caribou habitat schedule, habitat connectivity, harvest scheduling model I, woodland caribou, road network management

1. Introduction

Industrial forestry activities in Canada have caused habitat loss and negatively affected the abundance of some wildlife species, particularly boreal populations of woodland caribou (Rangifer tarandus caribou) (Vors et al. 2007). Clear-cut harvesting creates early successional regrowth, which attracts deer and moose, followed by predators that also prey on caribou (Wittmer et al. 2007; Beauchesne et al. 2013; Fryxell et al. 2020). Recovery efforts for caribou aim to manage landscapes to restore age–size distributions of forest patches suitable as caribou habitat and to eliminate movement corridors for predators (EC 2011, 2012).

Long-term policies designed to protect caribou in areas of industrial forestry aim to maintain large patches of mature conifer forest while aggregating harvest areas, as caribou tend to avoid disturbed sites (Dyer et al. 2001). This strategy provides an opportunity for separation from predators (Racey et al. 1999; OMNR 2009). However, the need to protect habitat for extended periods can reduce the area of productive forest available for harvesting or add scheduling constraints, leading to a trade-off between achieving forest management versus habitat protection goals in a forest landscape (Ruppert et al. 2016; Yemshanov et al. 2020).

In 2009, the Ontario Ministry of Natural Resources released the Caribou Conservation Plan (CCP) with directions to maintain naturally occurring low densities of alternate prey (moose and deer) and caribou predators (OMNR 2009). The CCP enhances the forest management planning process with a variety of tools and guidelines, such as the requirements for silviculture, harvest deferrals, decommissioning strategies for forest roads, and a dynamic caribou habitat schedule (DCHS) in the harvest plan. The DCHS is used primarily as a tool to encourage spatial separation of moose and deer from areas inhabited by caribou. Over several 20-year periods, the DCHS aggregates harvest disturbance into relatively few, compact regions distributed across entire forest management units, designed to be surrounded by areas with undisturbed habitat. The DCHS delineates harvest
regions over a long planning horizon and is updated every 10 years or sooner if there is a major disturbance (Martell et al. 1998; Baskent and Keles 2005).

Aggregating harvest within DCHS regions aims to maintain connectivity between undisturbed habitat surrounding the harvested areas, though it offers timber companies some flexibility to reallocate harvest within the regions. Currently, the DCHS does not incorporate a dynamic adjustment of harvest in response to rapidly changing economic conditions. Even distribution of DCHS regions across the entire managed area necessitates the construction of access roads to remote harvest locations, which has implications on the cost of timber supply. Once built, forest roads are likely to remain used by the public, and their continued availability increases the hunting efficiency of predators by allowing them to move farther and faster into caribou habitat (Courbin et al. 2009; Houle et al. 2010; Dickie et al. 2017).

An alternative to DCHS is the zoning approach, which protects caribou habitat by partitioning the forest landscape into a harvest deferral zone and an operational management zone where timber harvesting is permitted. A variant of the zoning approach is currently under consideration in the province of Québec, Canada, where caribou habitat would be maintained in contiguous areas near the northern limit of commercial forests in the boreal caribou range (GoC 2020; MFFP 2022). This approach considers the current state of the habitat while adjusting forestry practices to meet targets for restoring caribou habitat. Compared to the DCHS, this approach strives to defer harvest in large forest regions containing the high-quality habitat that is most crucial for caribou, and to temporarily protect habitat connectivity corridors. The management zone includes the areas with the highest levels of human disturbance, which helps reduce the harvest footprint. Periodically, the harvest deferral and management zones can be reconfigured in response to changes in habitat quality and forest composition.

In this study, we compared the DCHS and zoning approaches in terms of their habitat protection capacity and the cost of timber supply, under constraints consistent with current forest management planning practices, using optimization (Ohman 2000; McDill et al. 2016). Optimization models are frequently used in forest planning, including in situations where planners are faced with competing or conflicting objectives, such as maintaining adequate harvest levels but also sufficient habitat protection. For example, some models have addressed the habitat protection objective by applying habitat adjacency restrictions to harvested sites (McDill et al. 2002; Snyder and ReVelle 1997) and maximizing the area of protected habitat by selecting among the plausible habitat clusters (Tóth et al. 2009). Other models have enforced the connectivity of protected habitat by selecting a contiguous set of landscape patches that cover a desired habitat amount (Onal and Briers 2006) or maximizing the desired properties of the habitat network (Cerdeira et al. 2005; Toth et al. 2011).

A common approach to managing habitat connectivity in a forest planning problem is to depict a landscape as a spatial network of habitat patches interconnected by arcs—indicating potential wildlife movement corridors—and enforce connectivity between patches by solving a network flow model for the system (St. John et al. 2016; Yemshanov et al. 2020, 2021a, 2021b). This follows the approach outlined by Sessions (1992), which depicts the connected habitat as a Steiner network and finds a sub-graph of connected patches that maximizes a chosen conservation management metric under spatial and harvest planning constraints (St. John et al. 2016; Yemshanov et al. 2020, 2021a, 2021b). This network optimization approach also relates to the contiguous protected reserve problem of Jafari and Hearne (2013), as well as to the network flow models of Conrad et al. (2012) and Dilkina et al. (2016), which find minimum-cost corridors for a set of isolated habitats. Other studies solved a joint habitat protection and forest planning problem by applying a sequence of heuristic and optimization models (Ruppert et al. 2016; Martin et al. 2017). For each period, a heuristic model calculated the habitat priority map, followed by solving a harvest planning problem. At the next period, the harvest solution updated the forest composition and then the heuristic model was applied to calculate a new habitat map, followed by re-solving the harvest problem and so on.

We applied a network optimization approach to compare the DCHS and zoning approaches in the Wabadowgung Noopming Forest of Ontario, a boreal forest area with existing caribou habitat (Fig. 1). Our model formulation goes further than abovementioned examples and includes three sub-problems.
Fig. 2. An example of Dynamic Caribou Harvest Schedule (DCHS) regions for Wabadowgong Noopming Forest Management Unit. Region I can be harvested in any period. The protected areas with no DCHS plan are not shown. The map was created using ESRI ArcMap version 10.3. Base map layer was provided by NorthWinds.

that represent practical considerations in the face of somewhat conflicting objectives (e.g., the need for roads for harvest versus wildlife habitat protection). We formulate a harvest planning problem with habitat connectivity requirements, a protected area target and a set of harvest sustainability constraints, as prescribed in the Wabadowgong Noopming Forest Management Plan (FMP) (OMNR 2014a, 2014b; NorthWinds 2021). The harvesting problem finds the maximum timber volume that can be harvested, subject to sustainability requirements prescribed by the FMP. This formulation gives timber companies maximum flexibility of operations within the limits approved by the FMP. The actual harvest levels may be lower than these limits, and we have tested a scenario with the harvest volume levels anticipated in present conditions.

2. Materials and methods

Protecting caribou habitat in areas of clear-cut harvesting requires creation of interconnected undisturbed corridors that allow caribou to travel and avoid predators (Saher and Schmiegelow 2005; Beauchesne et al. 2013). Under the DCHS approach, this is achieved through even placement of compact harvestable regions across the landscape while retaining a matrix of unharvested forest between these regions. The harvestable status of regions is changed every 20 years (Fig. 2). By comparison, the zoning approach delineates larger areas with deferred harvest based on their assessed quality as caribou habitat, and these areas may stay undisturbed over longer periods. We conceptualize habitat protection in the zoning scenario as a connected pattern of protected forest habitat with the total protected area equal to a desired conservation threshold. We depict a forest landscape as a network of J forest patches (or nodes) over a timespan of U periods where any pair of adjacent patches containing habitat is connected by arcs. A patch i, j ∈ J, is characterized by the amount of suitable caribou habitat in period u, βju, u ∈ U, which is the habitat suitability to support caribou populations times the patch area.

Individual patches j must be sufficiently large to ensure the separation of caribou from predators (Lesmerises et al. 2013), so the patch size was set compatible with the daily distances covered by the animals (i.e., 5000–10 000 ha) (Rettie and Messier 2001; Rempel and Hornseth 2018). The suitability of habitat to support animals in patch j depends on the composition and age of the forest in j in period u (Ferguson and Elkie 2004a, 2004b; OMRF 2015). Clear-cut harvesting temporarily degrades the caribou habitat by increasing predation risk until forest cover matures in 40–60 years (Wittmer et al. 2005; Latham et al. 2011).

In each period u, the landscape J is divided into a harvest deferral zone Jdefe with interconnected habitat and a management zone Jmgmt where harvest is allowed. Zoning decisions are reconsidered for every period u. All patches in the harvest deferral zone in period u need to be connected. We depict the connectivity between adjacent patches j and k as a bi-directional pair of arcs, jk and kj, and conceptualize the connectivity between the patches as a flow through a sub-network of connected patches j in period u. A binary variable wkju indicates that flow can pass through an arc kj between patches k and j in period u in harvest deferral zone Jdefe. A non-negative variable ykju defines the amount of flow through arc kj. An auxiliary Node 0 is introduced to inject the flow into the sub-network of patches in zone Jdefe to maintain their connectivity. It is connected to all patches j and could pass the flow to any selected patch (Figs. 3a and 3e).

Similarly, all patches in the management zone Jmgmt must be accessible from locations where permanent roads enter the area, which enforces the contiguity of set Jmgmt. A binary variable Vju defines the connection between the patches k and j in the management zone Jmgmt, and a non-negative variable zkju characterizes the flow amount through arc kj in period u. The management and harvest deferral zones do not overlap except at Node 0 (Fig. 3e).

The zoning problem allocates the connected harvest deferral and management zones to maximize the amount of habitat in the deferral zone, subject to the target area proportion designated for habitat protection, δ, δ ∈ [0;1], i.e.,

\[
\max f_1 \sum_{u \in U} \sum_{j \in J} \sum_{k \in Q} (w_{kj} \beta_{ju}) - \sum_{u \in U} f_2 (p_{1u} + p_{2u})
\]

such that

Set \( N_j \) includes harvestable sites \( n \) located in patch \( j \). When patch \( j \) is in the harvest deferral zone, no harvest is allowed at any site \( n \) inside patch \( j \); (e) connectivity network between patches \( j \) and an example of network flow from Node 0 through the selected connected patches in the harvest deferral and the management zones. Figs. 3c–3e depict the same area.
(4) \[ p_{1u} \geq \sum_{j \in Q} w_{0ju} - 1 \quad \forall \ u \in U \]

(5) \[ p_{2u} \geq \sum_{j \in Q} v_{0ju} - \theta \quad \forall \ u \in U \]

(6) \[ \sum_{k \in Q} v_{kju} + \sum_{k \in Q} w_{kju} = 1 \quad \forall \ j \in J, \ u \in U \]

(7) \[ \sum_{k \in Q} v_{kju} \geq \omega_j \quad \forall \ u \in U, j \in J \]

(8) \[ \sum_{j, u} \Phi_j \sum_{k \in Q} v_{kju} \geq 1 \quad \forall \ u \in U \]

(9) \[ 0.95 \delta \sum_{j \in J} \alpha_j \leq \sum_{j \in J} \sum_{k \in Q} (w_{kju} \alpha_j^k) \leq \delta \sum_{j \in J} \alpha_j \quad \forall \ u \in U \]

Objective (1) maximizes the total amount of connected habitat in the area minus the penalties \(p_{1u}\) and \(p_{2u}\) (see Appendix A). Penalty \(p_{1u}\) denotes the number of connections to Node 0 above one in the deferral zone in period \(u\). Penalty \(p_{2u}\) defines the number of connections to Node 0 in the management zone above \(\theta\) nodes in period \(u\), where \(\theta\) is the total number of nodes with access points where roads enter the managed area. The coefficients \(f_1\) and \(f_2\) are scaling factors that adjust, respectively, the relative priorities for the objective term and the penalties (Appendix A). Table 1 lists the symbolic notations.

Equations 2 and 3 specify that the harvest deferral and management zones \(J_{\text{def}r}\) and \(J_{\text{mgmt}}\) must each be contiguous (see the formulation of eqs. 2 and 3 in eqs. A2.1–A2.4 and A3.1–A3.4 in Appendix A). Constraints (4, 5) define penalties \(p_{1u}\) and \(p_{2u}\). Constraint (6) specifies that patch \(j\) can only be a member of the harvest deferral or management zone in period \(u\) but not both. Subset \(Q_j\) denotes patches \(k\) and an auxiliary Node 0 that are connected to patch \(j\) and can transmit flow to \(j\) (Fig. 3b). Constraint (7) ensures that the management zone includes patches \(j\) with permanent roads, as identified by the binary parameter \(\omega_j = 1\). Constraint (8) specifies that the management zone includes at least one patch in period \(u\) where roads enter the area. A binary parameter \(\Phi_j = 1\) defines patches \(j\) with access points where permanent roads enter the area. Constraint (9) sets the target proportion of the harvest deferral area in period \(u\) to \([0.95\delta; \delta]\), where \(\alpha_j\) is the area of patch \(j\).

2.1. Harvest planning model

Forest sites in the management zone can be harvested for timber. In boreal Canada, harvest planning is implemented at the scale of individual clear-cut blocks (NFD 2019). We depict the landscape as a set of \(N\) harvestable forest sites \(n\) covering the same area as the \(J\) patches in the zoning problem (eqs. 1–9) (Fig. 3c). The area of harvestable site \(n\) is smaller than the area of patch \(j\) (Fig. 3c); each patch \(j\) includes \(N_j\) sites \(n\) (Fig. 3d).

The harvest schedule covers a timespan of \(T\) periods, \(t = 1, \ldots, |T|\), where \(|T|\) is a cardinality of set \(T\). We only consider clear-cut harvest, which is the most common harvest type in Canada (NFD 2019), and assume binary harvest decisions in site \(n\). For each site \(n\), with a forested area \(a_n\), we define a set of harvest prescriptions \(I, i = 1, \ldots, |I|\), that represents all possible sequences of silvicultural events over a timespan \(T\). A binary variable \(x_{ni}\) selects whether a prescription \(i\) is applied in site \(n\) over \(T\) periods.

For each site \(n\), prescription \(i\) provides tree species composition, age, the volume of harvested softwood (\(\gamma_{1ni}\)) and hardwood (\(\gamma_{2ni}\)) timber in period \(t\), and a cash flow \(\psi_n\) from harvesting \(n\) over \(T\) periods minus harvest, hauling, and regeneration costs, i.e.,

\[ \phi_n = \alpha_n \left( \gamma_{1ni} (\rho_1 - \sigma_{1n}) + \gamma_{2ni} (\rho_2 - \sigma_{2n}) - \eta_{ni} \right) \]

Symbols \(\rho_1\) and \(\rho_2\) denote the mill gate timber unit prices for softwoods and hardwoods, \(\sigma_{1n}\) and \(\sigma_{2n}\) are the respective hauling unit costs from site \(n\), and \(\eta_{ni}\) is the post-harvest regeneration cost. We estimate undiscounted cash flow \(\psi_n\) to avoid decisions prioritizing near-term profits and undervaluing long-term sustainability of harvest. The tree species composition and age define the amount of suitable caribou habitat in site \(n\) in period \(t\), \(\beta_{ni}\). We also used the site-based habitat amounts \(\beta_{ni}\) to calculate the amounts of habitat in patches \(j\) in periods \(u\), \(\beta_j\), in the zoning problem (eqs. 1–9).

We adapted the harvest scheduling Model I formulation (McDill et al. 2016) to find an optimal set of harvest prescriptions for area \(N\) over timespan \(T\). Our harvesting problem maximizes net cash flow from managing the forest area \(N\) over \(T\) periods, i.e.,

\[ \max \sum_{n \in N} \sum_{i \in I} \phi_n x_{ni} \]

s.t.:

\[ \sum_{i \in I} x_{ni} = 1 \quad \forall \ n \in N \]

\[ 0.85m \leq \sum_{n \in N} \sum_{i \in I} \left( \gamma_{1ni} + \gamma_{2ni} \right) x_{ni} \leq m \quad \forall t \in T \]

\[ \sum_{n \in N} \left( \left| \psi_n - \psi_{T_{min}} \right| \right) x_{ni} \geq 0 \]

Constraint (12) ensures that each forest site \(n\) is assigned one prescription only. A non-negative decision variable \(m\) defines the maximum volume of timber that can be harvested in any combination of the area and period \(t\). Constraint (13) limits the allowable departure from the maximum harvest level \(m\) to 15%. We introduce a minimum average age of forest stands in area \(N\) at the end of planning horizon \(T\), \(\epsilon_{T_{\text{min}}}\), and define \(\epsilon_n\) as the forest stand age in site \(n\) at the end of the planning horizon in prescription \(i\), \(t = |T|\). Constraint (14) ensures that the average age of forest stands in area \(N\) at the end of the horizon \(t = |T|\) is greater than or equal to the target age \(\epsilon_{T_{\text{min}}}\).

Forest age composition in area \(N\) needs to be aligned with FMP requirements (NorthWinds 2021), which control the composition over planning horizon \(T\) at the level of forest type (Appendix B). We define a set of \(G\) forest types \(g\), \(g \in G\) ([\(G\)=4 types in this case study, see Appendix B]), and calculate the areas of mature and old-growth stands, \(x_{g_{\text{ma}}}\) and \(x_{g_{\text{ol}}}\), for

#### Decision variables

$w_{jk}$ Binary indicator of the connection via an arc $jk$ in period $u$ in the harvest deferral zone $w_{jku} \in \{0,1\}$

$y_{ju}$ Amount of flow between the adjacent patches $j$ and $k$ in period $u$ in the harvest deferral zone $y_{ju} \geq 0$

$x_{ni}$ Binary selection of harvest schedule $i$ in site $n$ $x_{ni} \in \{0,1\}$

$z_{ku}$ Binary indicator of the connection via an arc $kj$ in the management zone in period $u$ $z_{ku} \in \{0,1\}$

$z_{ku}$ Amount of flow between the adjacent patches $k$ and $j$ in the management zone in period $u$ $z_{ju} \geq 0$

$\theta_{kt}$ Binary indicator of the flow through arc $k$ (denotes road construction in $j$) in period $t$ $\theta_{kt} \in \{0,1\}$

$\theta_{kt}$ Amount of flow between patches $k$ and $j$ when a road is built from $k$ to $j$ in period $t$ $\theta_{kt} \geq 0$

$\alpha_u$ Maximum volume of timber that can be harvested in any combination of area $N$ and period $t$ $\alpha_u \geq 0$

$\phi_i$ Penalty on the number of connections to Node 0 above one in the harvest deferral zone in period $u$ $\phi_i \geq 0$

$\psi_i$ Penalty on the number of connections to Node 0 above $\theta$ in the management zone in period $u$ $\psi_i \geq 0$

$\Omega_{it}$ Penalty on the number of patches with roads built above the defined maximum limit $\tau$ in period $t$ $\Omega_{it} \geq 0$

#### Parameters: binary indicators

$\Phi_j$ Binary indicator of patches $j$ with access points where permanent roads enter the area $\Phi_j \in \{0,1\}$

$\Psi_j$ Binary indicator of patches $j$ with permanent roads $\Psi_j \in \{0,1\}$

$\Gamma_j$ Binary indicator of patches $j$ with permanent or temporary roads existing in period $t = 1$ $\Gamma_j \in \{0,1\}$

$\Lambda_{nj}$ Binary indicator that harvest site $n$, $n \in N$ is in patch $j$, $j \in J$ $\Lambda_{nj} \in \{0,1\}$

$\Xi_{ut}$ Binary time overlap between period $u$ in the zoning problem and period $t$ in harvest planning problem $\Xi_{ut} \in \{0,1\}$

$\Xi_{nit}$ Binary indicator that site $n$ is harvested in period $t$ in prescription $i$ $\Xi_{nit} \in \{0,1\}$

$\Omega_{nit}$ Binary indicator that site $n$ is harvestable in period $t$ according to the static Dynamic Caribou Harvest Schedule plan $\Omega_{nit} \in \{0,1\}$

#### Other parameters

$\beta_{nit}$ Amount of habitat in site $n$ in prescription $i$ in period $t$ $\beta_{nit} \geq 0$

$\delta_{nit}$ Amount of habitat $\delta_{nit}$ in patch $j$ in period $u$ (the habitat quality times the patch area) $\delta_{nit} \geq 0$

$\alpha_n$ Forest area in harvest site $n$ $\alpha_n \geq 0$

$\alpha_j$ Area of patch $j$ $\alpha_j > 0$

$\chi_{gnt}$ Area of mature stands of forest type $g$ in site $n$ in prescription $i$ in period $t$ $\chi_{gnt} > 0$

$\xi_{gnt}$ Area of old-growth stands of forest type $g$ in site $n$ in prescription $i$ in period $t$ $\xi_{gnt} > 0$

$\xi_{nit}$ Area of young forest stands in site $n$ in prescription $i$ in period $t$ $\xi_{nit} > 0$

$\gamma_{nit}$ Volume of softwood timber available for the harvest at a patch $n$ in period $t$ in prescription $i$ $\gamma_{nit} \geq 0$

$\gamma_{nit}$ Volume of hardwood timber available for the harvest at a patch $n$ in period $t$ in prescription $i$ $\gamma_{nit} \geq 0$

$\psi_{nit}$ Net cash flow associated with harvesting a patch $n$ according to prescription $i$ $\psi_{nit} \geq 0$

$\epsilon_{nit}$ Forest stand age in a site $n$ at the end of the planning horizon if prescription $i$ is applied $\epsilon_{nit} \in [0;220]$

$\epsilon_{min}$ Average target age of forest stands in the managed area at the end of the planning horizon $T$ $\epsilon_{min} > 80$

$\delta$ Target proportion of the harvest deferral area in any period $u$ $\delta \in [0;1]$

$\rho_1$ Unit price for softwood timber at the mill gate $\rho_1 = \$700 \text{ m}^{-3}$

$\rho_2$ Unit price for hardwood timber at the mill gate $\rho_2 = \$500 \text{ m}^{-3}$

$\eta_{nit}$ Post-harvest regeneration cost in site $n$ in prescription $i$ in period $t$ $\eta_{nit} \geq 0$

$\sigma_{1n}, \sigma_{2n}$ Hauling and harvest unit cost at site $n$ for softwood and hardwood timber $\sigma_{1n}, \sigma_{2n} > 0$
each forest type $g$ in site $n$ in prescription $i$ in period $t$. Constraints (15) and (16) set the minimum target areas $\chi_{\text{min}}$ and $\xi_{\text{min}}$ for mature and old-growth stands in forest type $g$ in period $t$ according to the FMP, i.e.,

$$\sum_{n \in N} \sum_{i \in I} \chi_{\text{min}} x_{ni} \geq \chi_{\text{min}} \quad \forall \ t \in T, g \in G$$

$$\sum_{n \in N} \sum_{i \in I} \xi_{\text{min}} x_{ni} \geq \xi_{\text{min}} \quad \forall \ t \in T, g \in G$$

The FMP also limits the maximum area of young stands in the area, $\xi_{\text{max}}$, i.e.,

$$\sum_{n \in N} \sum_{i \in I} \xi_{\text{max}} x_{ni} \leq \xi_{\text{max}} \quad \forall \ t \in T$$

where $\xi_{\text{min}}$ denotes the area of young stands in site $n$ in prescription $i$ in period $t$.

Conifer stands, which represent suitable habitat for caribou (Appendix B) but also high timber value, may not always regenerate after harvest (Harvey and Bergeron 1989; Carleton and MacCallan 1994). Replanting enhances regeneration of conifer stands but is costly. A common practice to cover regeneration costs incurred in site $n$ in prescription $i$ in period $t$ is to allocate a portion of timber revenue via fixed payments per unit of harvested timber to a special fund that pays for replanting. Thus, the replanting budget depends on the volume of timber harvested in period $t$ and cannot exceed the sum of payments to the special fund from harvest revenue, i.e.,

$$\sum_{n \in N} \sum_{i \in I} \alpha_i \eta_{\text{init}} x_{ni} \leq \sum_{n \in N} \sum_{i \in I} (\alpha_i \eta_{\text{init}} (\gamma_{\text{init}} \psi_1 + \gamma_{\text{init}} \psi_2)) \quad \forall \ t \in T$$

where symbols $\psi_1$ and $\psi_2$ denote the fixed payments per unit of harvested softwood and hardwood timber, respectively, to the special fund. Note that the cash flow value $\psi_{\text{init}}$ in objective (11) already accounts for the regeneration cost $\eta_{\text{init}}$ incurred in site $n$ in prescription $i$ in period $t$. Since we have two regeneration options, the prescriptions $l$ include two subsets with natural regeneration and replanting of harvested sites for all sequences of silvicultural events in sites $n$ (Appendix B).

### 2.2. Road construction

Harvesting remote areas requires building access roads. We adapted the model of Yemshanov et al. (2022) to track expansion of the forest road network over timespan $T$. To reduce combinatorial complexity, we implement the road construc-

subject to constraints (2–9, 12–27) and

\[
\frac{1}{M} \sum_{n \in N} \left( \Lambda_{nj} \sum_{i \in I} \left( \chi_{ni} X_{nit} \right) \right) \leq 1 - \sum_{k \in Q} w_{2ju} \quad \forall \, j \in J, \, u \in U
\]

The first term in objective (28) estimates the total amount of habitat, the second term denotes harvest revenue minus the road construction and maintenance cost, and the last two terms depict the penalties. Symbol \( \pi_j \) denotes the road maintenance cost in patch \( j \) in period \( t \). Since the habitat amount and harvest revenue have different units, we needed a scaling factor \( f_1 \) to balance the terms in the objective equation. The scaling factor \( f_1 \) is set to 0.1 to give harvest revenue a slight priority over habitat protection. The use of penalties \( p_{1u}, p_{2u}, \) and \( p_{3t} \) in the full problem (2–9, 12–28) is intended to keep the solution feasible in the presence of errors in the spatial data that otherwise would cause violations of hard constraints. In this context, the scaling factors \( f_2 \) and \( f_3 \) should be set sufficiently high to push the model towards a solution with zero penalties under normal circumstances. The penalties would be positive in the presence of complex patterns in the underlying spatial data (such as the presence of isolated harvestable regions or habitat refugia surrounded by the management zone). The penalty formulation of the constraints in the network flow sub-problems also helps reduce the time to find a feasible solution compared to a hard constraint formulation. Constraint (29) ensures no harvesting in patches \( j \) as assigned to the harvest deferral zone in period \( u \).

We modified the zoning problem (2–9, 12–28) to follow the DCHS policy that restricts harvest in site \( n \) in period \( t \) to a fixed schedule outlined in the area’s FMP (Fig. 2). For each harvest site \( n \), a binary parameter \( \Xi_{nit} \) defines whether a site \( n \) can be harvested in period \( t \) according to the DCHS plan (\( \Omega_{nit} = 1 \) and \( \Omega_{nit} = 0 \) otherwise). Constraint (30) restricts harvest in period \( t \) to regions prescribed by the DCHS plan, i.e.,

\[
\sum_{i \in I} \chi_{ni} X_{nit} \leq \Omega_{nit} \quad \forall \, t \in T, \, n \in N
\]

The left side of eq. 30 defines the number of harvest events in site \( n \) over horizon \( T \) in prescription \( i \).

The DCHS scenario maximizes the cash flow from timber harvest net of road construction and maintenance costs, i.e.,

\[
\max_{n \in N} \sum_{i \in I} \sum_{j \in J} \left( \phi_{niu} X_{nit} \right) - \sum_{i \in I} \sum_{j \in J} \left( b_{ji} \pi_j + \lambda_j \sum_{k \in Q} h_{kg} \right) - \sum_{i \in I} \left( f_2 P_{1u} + f_3 P_{3t} \right)
\]

subject to constraints (12–24, 27, 30) and

\[
\sum_{k \in Q} h_{kg} \leq \sum_{n \in N} \left( \Lambda_{nj} \sum_{i \in I} \left( \chi_{ni} X_{nit} \right) \right) \quad \forall \, j \in J, \, t \in T
\]

Constraint (32) allows road construction to patch \( j \) in period \( t \) only if there is one or more harvest events in patch \( j \) during that period. While the DCHS plan was applied to a set of defined DCHS regions (Fig. 2), road construction was tracked at the scale of patches \( j \) (Fig. 4a). Note that our DCHS scenario
Fig. 4. Model spatial inputs: (a) patches $j$ with major roads at time $t = 0$; (b) habitat patch connectivity network in the harvest deferral zone; (c) site access network in the management zone; (d) hauling times for hardwood timber, hours; (e) hauling times for softwood timber, hours; (f) habitat amount $\beta_{nit}$ at $t = 0$; (g) forest stand age at $t = 0$. does not track habitat degradation by roads built through DCHS regions that were not harvested.

The DCHS problem is simpler than the full zoning problem, so we solved it first under the ecological constraints prescribed by the FMP. We then solved a series of zoning problems using the same set of ecological constraints and selected the solution with the harvested timber volume closest to the DCHS solution so that both scenarios harvested roughly the same volume of timber. We also evaluated a selected solution with the harvested timber volume closest to the DCHS solution and the proportion of young stands \( \leq 40 \) years old, \( \xi_{nit} \), from age and forest composition data generated for prescriptions \( i \) (Table 3).

2.4. Case study

We compared the DCHS and zoning policies in the Wabadowgang Noopming Forest Management Unit (FMU) in northwestern Ontario, Canada (Fig. 1). The area overlaps parts of the Nipigon and Brightsand caribou ranges (OMNR 2012) and is moderately fragmented by harvesting. The nearest timber markets include a sawmill and a pulp mill owned by Resolute Forest Products in Thunder Bay, Ontario, and a proposed wood pellet plant in Armstrong, Ontario (Neegan Burnside 2014; Bieler et al. 2019).

We estimated the starting values for age, timber volume, and land cover composition from Ontario’s Forest Resource Inventory database (OMNR 2020). The FMU area included 30,393 harvestable sites \( n \). To estimate future timber volumes in harvest prescriptions, we applied yield curves for northwestern Ontario described in the Wabadowgang Noopming FMP (NorthWinds 2021). We adjusted the timber volume by the projected annual losses of forested area due to wildfires using fire regime zones from Boulanger et al. (2014). Future forest composition was adjusted by forest succession rules based on descriptions in the FMP (Appendix B).

Previous assessments of caribou movement patterns in Ontario suggested that individuals move regularly over relatively broad regions (Hornseth and Rempel 2015). Therefore, we depicted patches \( J \) as a network of 986,000 ha hexagons (Figs. 4a–4c). We used the CanVec database (NRCan 2019) and data provided by NorthWinds Environmental Services to estimate the locations of major roads (Fig. 4a). We chose a relatively coarse resolution of the road network to reduce the combinatorial complexity of the problem. The road expansion problem tracked the average per-unit road construction and maintenance cost in patch \( j \). Based on estimates provided by Resolute Forest Products (M. Kaiser, pers. comm.), the average road construction cost in patch \( j \) was set to $29,000 km\(^{-1}\) (all costs are in Canadian dollars). Road maintenance costs for patch \( j \) were estimated at $3500 km\(^{-1}\) for each period when harvest occurred in \( j \). The road cost value in patch \( j \) was based on an estimated median road length of 29 km patch\(^{-1}\).

Hauling costs included an on-site harvest cost of $24.75 m\(^{-3}\) and costs for delivery of hardwood timber to a proposed pellet plant in Armstrong, Ontario, and softwood timber to mills in Thunder Bay, Ontario (Figs. 4d and 4e). The hauling costs assumed an hourly rate of $125 h\(^{-1}\), a load capacity of 41 tonne, and 30 min of time each to load, check, and unload harvested timber (M. Kaiser, pers. comm.) (Table 2).

The planning horizon \( T \) included 15 × 10-year planning periods. The planning period \( u \) in the zoning problem (1–15) was set to 30 years, each of which included three harvest planning periods \( t \), for a total of five periods \( u \) over a 150-year timespan. We used Ontario’s Forest Resource Inventory (FRI) database (OMNRF 2020) to calculate the amount of suitable habitat for caribou in current conditions (Fig. 4f). Each forest site in the FRI was classified as one of 13 “forest units” that depict forest landscape composition classes (OMNR 2014a) (see Appendix B). Using forest composition and age, we estimated the amount of suitable caribou habitat in site \( n \) in period \( t \) in prescription \( i \), \( b_{nit} \), using a caribou habitat model for Ontario’s Northwest Region (Elkie et al. 2018) (Appendix B).

Areas of mature and old-growth forest were tracked at the level of four general forest types \( g \) (Figs. 4h–4k): stands dominated by balsam fir; the lowland conifer group (black spruce and other conifer-dominated stands in poorly drained sites); the upland conifer group (conifer-dominated stands in other topographical positions); and the hardwood group dominated by deciduous species. For each site \( n \), we estimated the areas of each forest group \( g \) reaching mature and old-growth status in prescription \( i \) in period \( t \), \( \chi_{gnit} \) and \( \delta_{gnit} \), and the proportion of young stands \( \leq 40 \) years old, \( \xi_{nit} \), from age and forest composition data generated for prescriptions \( i \) (Table 3).

3. Results

The DCHS and zoning solutions harvested roughly the same volume of timber (Table 4) but applied different spatial approaches to allocate broad harvest regions (Fig. 5). The DCHS solution distributed the harvestable regions across the entire FMU area according to a pre-defined plan (Fig. 2) to ensure that each region was harvested at least once over a 100-year timespan. The zoning solution allocated the harvest deferral zone in areas with the largest amounts of suitable habitat, and frequently over a longer term. While the deferral zone was reconfigured every 30 years (Fig. 6a), 40.2% of the FMU area was kept unharvested for...

120 years or longer (Table 5). Changes in the configuration of the deferral zone were driven by changes in habitat suitability patterns and local timber availability through time (Fig. 6b).

In general, the DCHS plan aims to keep 40% of the area as a no-harvest zone with average forest age above 60 years, which translates to an 80–100-year timespan without harvest over a 150-year horizon (Table 5, Fig. 7a). In the DCHS scenario, 19% of the area was exempt from DCHS and eligible to be harvested at any time (Fig. 2, callout I). A similar harvest regime was allocated to 39.4% of the area in the zoning scenario (Fig. 7b). The maximum timespan without harvesting in the DCHS scenario was 100 years, whereas the zoning scenario was able to keep 39.3% of the FMU area without harvest for the entire horizon (150 years). These areas were located near parks and nature reserves and included the highest-quality habitat for caribou. In each planning period, the deferral zone remained connected (Figs. 6b and 7b). Note that our habitat connectivity network \( J \) allowed habitat to be connected through the protected reserves and provincial parks adjacent to the harvestable areas (Fig. 4b). This led to the creation of two deferral regions, one along the northern FMU border and a smaller region in the southeastern part of the FMU that is adjacent to nature reserves along the northern shores of Lake Nipigon (Fig. 7b). The management zone included the fragmented areas with existing roads and previous history of harvest in the southern and central parts of the area (Figs. 6a and 7b).

The maximum level of sustainable harvest in the DCHS and zoning scenarios was 0.25 M m\(^{-3}\) year\(^{-1}\), including 0.15 M m\(^{-3}\) year\(^{-1}\) of softwoods (Table 4). At this level, the zoning scenario maintained the habitat in the harvest deferral zone over approximately 46% of the area in any period \( t \). The bulk of the harvest was allocated close to the network of logging roads in the southern and central portions of the FMU (Fig. 5b). By design, the harvestable regions in the DCHS scenario were distributed across the entire FMU area (Fig. 5a), which necessitated building a larger network of forest roads than in the zoning scenario (Table 4, Fig. 8a). The road construction provided access to a larger footprint than in the zoning scenario (Figs. 7c and 7d). The peak period of road construction activities lasted longer in the DCHS scenario, and these activities cost more than that in the zoning scenario (Table 4, Fig. 8a).

The zoning scenario had 19% less area designated for habitat protection in any period \( t \), yet the area accounted for...

* Limiting the harvest volume of softwoods to 0.12 m$^3$·year$^{-1}$.

† The zoning solution used a configuration of the harvest deferral and management zone from the maximum sustainable harvest solution.

Increasingly, Canadian provinces and territories aim to reduce the negative impacts of forestry activities on boreal caribou populations by developing dynamic forest plans that account for habitat connectivity and suitability. Our study evaluated two distinct but practical management policies that strive to protect caribou populations in areas of forestry roughly the same amount of habitat $\beta_{nit}$ (which is the habitat quality times patch area) (Table 4, Fig. 8a). This is because the zoning scenario protected the highest-quality habitat in the deferral zone while concentrating the harvest in a 15% smaller footprint than in the DCHS scenario.

The timber supply unit cost in the zoning scenario was $1.24 m$^{-3}$ cheaper than in the DCHS scenario (Table 4). This difference, while small, approaches the royalties that timber companies pay to the province for harvesting Grade 2 timber according to Ontario Crown Timber Charges (OMNRF 2022). The cost difference was mainly due to higher road construction costs and a less flexible harvest schedule in the DCHS scenario, which does not permit full utilization of the available timber supply in the area.

The replanting budgets were close in both scenarios and characterized by similar dynamics (Fig. 8b). The zoning scenario utilized the entire replanting budget (97.9%), whereas the DCHS scenario utilized a lower percentage of the budget (82.8%) (Table 4). Replanting is more cost-effective in the zoning scenario because the harvest occurred over a smaller area than in the DCHS scenario.

The behavior of the solutions with present-day harvest levels resembled the solutions with maximum sustainable harvest levels (Table 4). These solutions harvested 0.11 M m$^{-3}$·year$^{-1}$ of softwoods and 0.05 M m$^{-3}$·year$^{-1}$ of hardwood species and fully utilized the replanting budget. The timber supply unit cost in the zoning solution was $2.22 m$^{-3}$ lower than in the DCHS solution. Both solutions protected the same amount of habitat (Table 4).

The DCHS and zoning scenarios used the same set of ecological constraints, which explains the relatively minor differences in forest age structure between scenarios (Fig. 8c). Over the long term, the zoning scenario protected a larger area of old-growth forests but created more young forest stands in the FMU. This is because the harvest was concentrated in a smaller area, while a significant portion of the FMU in the deferral zone was left unharvested over a long period.

We did not find significant differences in the composition of broad forest types $g$ over time between the DCHS and zoning scenarios (Fig. 9a). Over the long term, the zoning scenario protected a larger area of old-growth and mature upland conifer stands (Fig. 9b) and a larger area of old-growth hardwood-dominated stands (Fig. 9c). This is a result of long harvest deferral periods across more than 39% of the FMU under the zoning approach. Since high-quality habitat for caribou is often represented by mature and old conifer-dominated stands, setting aside a larger area of these for habitat protection also helps attain the old-growth conservation objective.

4. Discussion

Increasingly, Canadian provinces and territories aim to reduce the negative impacts of forestry activities on boreal caribou populations by developing dynamic forest plans that account for habitat connectivity and suitability. Our study evaluated two distinct but practical management policies that strive to protect caribou populations in areas of forestry

Table 5. Proportion of the Forest Management Unit area by the continuous protection timespan (years) in Dynamic Caribou Harvest Schedule (DCHS) and zoning scenarios.

Our intent was not to emphasize the advantages of either approach but instead offer a methodological framework to compare these (and potentially other) landscape management policies. The use of the same set of ecological constraints aligned with the FMP enabled a fair comparison between the two scenarios.

The DCHS approach concentrates harvest in compact regions distributed across the entire FMU but establishes undisturbed caribou habitat around these harvested areas. With the primary goal of protecting caribou populations, the DCHS may overlook several economic aspects that impact the cost of timber supply. Since the DCHS harvest regions are distributed across the entire FMU area, this requires building and maintaining a network of access roads, which increases the cost of timber supply. Furthermore, the DCHS, while trying to protect a desired proportion of the unharvested forest area, has limited flexibility to adjust the timing and harvest locations in response to rapid changes in forest composition or market-driven timber demand. As shown in a previous study (Yemshanov et al. 2021a), finding the optimal timing of harvest in DCHS regions helps reduce the timber supply cost but poses a hard combinatorial problem that requires further work to make the approach practical. The DCHS scenario was able to maintain a larger unharvested area than the zoning scenario. However, the network of access roads created in the DCHS scenario is likely to promote both human and predator access to undisturbed areas and, in turn, place further pressure on caribou populations (Dickie et al. 2017).

An alternative zoning approach divides the landscape into management and harvest deferral zones without enforcing the allocation of harvest regions across the FMU. Within the management zone, timber companies have flexibility to reallocate harvest in response to rapid changes in timber markets. Our results indicate that the zoning approach yields a lower timber cost than the DCHS scenario. The difference was relatively small in our case study because the DCHS scenario excluded the south-central portion of the FMU from the DCHS rules (Fig. 2, callout I). This region occupies 19% of the FMU area and has a fully flexible harvest regime. The impact of the DCHS rules on timber cost would be more significant if the entire FMU area was subject to these rules.

In our zoning scenario, the configuration of the road network and the distribution of high-quality caribou habitat translated to a relatively stable designation of the harvest deferral and management zones over time. Semi-permanent allocation of the zones over time helps facilitate long-term protection of high-quality caribou habitat. Although the zoning scenario protected less total area than the DCHS scenario in any period $t$, it protected virtually all areas with high concentrations of highly suitable habitat.

Our simulations did not account for all possible factors that might come into play for boreal caribou management. First, compared to the DCHS, the zoning approach protects less undisturbed habitat as defined in the recovery strategy for boreal caribou (EC 2012) that prescribes a 65% undisturbed habitat threshold. Note that this threshold applies to entire caribou ranges (which is a broader scale than the extent of activities.
Fig. 7. Continuous timespan without harvesting, years: (a) Dynamic Caribou Harvest Schedule (DCHS) scenario and (b) zoning scenario. - No roads

Our study). Other areas outside of the FMU (such as parks and protected reserves) may contribute to achieving this conservation management threshold. Nevertheless, there exists a risk that a zoning approach may eventually exclude caribou from intensive management zones and push animals to harvest deferral zones, further reducing their distribution range (Schaefer 2003; EC 2012). The DCHS allows for a better interspersion of management and conservation zones at the landscape scale, potentially supporting the co-occurrence of caribou and timber management over long temporal scales. However, DCHS promotes more road construction and maintains forests at a younger age, on average, than the zoning approach, meaning that alternate prey and predator species may be favored to the detriment of caribou (Wittmer et al. 2007). These trade-offs will need to be further evaluated in the context of caribou conservation. Furthermore, increasing the forest age in the harvest deferral zone is likely to increase the fire risk as the fuel accumulation period gets longer. The zoning approach would likely fail if economic and political pressures triggered the harvesting in the protection zones before the end of the harvest plan (here, 150 years). This risk is always present, as timber industries may struggle to adapt to external pressures of changes in timber markets and climate change (Brecka et al. 2020).

Our model formulation followed the ecological sustainability prescriptions as defined in the FMP but used simpler forest succession rules at the level of major forest types than the succession rules in the plan. In addition, the model tracked the road construction cost at a coarse spatial resolution of habitat patches \( j \), which might misrepresent local road costs in some areas. The coarse resolution helped reduce the computational complexity of the road construction problem, which is known to be combinatorically hard. Potentially, the problem could be formulated at a higher spatial resolution than patches \( j \), but this would require introducing another network set and further increase the problem complexity. Since we aimed to track the general road construction feedback at a scale compatible with the size of DCHS regions, the use of a coarse resolution felt justified.
Fig. 8. The dynamics of road construction and replanting costs, habitat amounts, and the proportions of major forest age groups over time \( t \): (a) habitat amount and road construction and maintenance cost; (b) the replanting budget and actual cost; and (c) FMU area proportion occupied by mature, old-growth, and young forest stands.

Fig. 9. Area of major forest types in planning periods \( t \): (a) total area, by forest type, ha; (b) the area of old-growth stands, by forest type, ha; and (c) the area of mature stands, by forest type, ha. General forest types: fir-dominated (in blue), upland conifer (in gray), lowland conifer (in green), and hardwood (in red).

APPENDIX A. The habitat connectivity and road construction models

1. Habitat connectivity and site access model

Protecting caribou habitat in areas of clear-cut harvesting requires creation of interconnected, undisturbed corridors that allow caribou to travel and avoid predators. The zoning approach divides the landscape into (i) areas with deferred harvesting based on their assessed quality as caribou habitat and which may stay undisturbed over longer periods and (ii) a management zone where harvesting is allowed. We conceptualize the protected habitat area in the zoning scenario as a connected pattern of protected forest with a total area equal to a desired conservation management threshold. We depict a forest landscape as a network of forest patches (nodes) over a timespan of $U$ periods where any pair of adjacent patches containing habitat is connected by arcs. A patch $j$, $j \in J$, is characterized by the amount of suitable caribou habitat in period $u$, $\beta_{ju}$, $u \in U$, which is the habitat suitability (i.e., to support caribou populations) times the patch area. The suitability of habitat to support caribou in patch $j$ depends on the composition and age of the forest in $j$ in period $u$. Clear-cut harvesting temporarily degrades the caribou habitat by increasing predation risk until forest cover matures in 40–60 years.

In each period $u$, the landscape $j$ is divided into a harvest deferral zone with interconnected habitat and a management zone where harvest is allowed. Zoning decisions are considered every period $u$. All habitat patches in the harvest deferral zone in period $u$ need to be connected. We depict the connectivity between adjacent patches $j$ and $k$ as a bi-directional pair of arcs, $jk$ and $kj$, and conceptualize the ability of caribou to move between the protected patches as a flow through a sub-network of connected patches $j$ in period $u$. A binary variable $w_{ju}$ indicates that flow can pass through an arc $kj$ connecting adjacent patches $k$ and $j$ in period $u$. A non-negative variable $y_{ju}$ defines the amount of flow through arc $kj$. Connectivity between the patches is maintained by injecting the flow into one protected patch and ensuring that all other protected patches receive flow from that patch (Fig. 3a in the main text). An auxiliary Node 0 injects flow into the sub-network of patches in the harvest deferral zone to maintain their connectivity. Node 0 is connected to all patches $j$ and can pass the flow to any selected patch (Fig. 3a in the main text). A patch $j$ is a member of the harvest deferral zone if it receives incoming flow from any connected protected patch $k$ or Node 0.

Similarly, all patches in the management zone need to be accessible from patches with roads, which requires enforcing connectivity between patches in the management zone. A binary variable $v_{ju}$ defines the connection between the adjacent patches $k$ and $j$ in the management zone and a non-negative variable $z_{ju}$ characterizes the amount of flow through arc $kj$ in period $u$. The subnetworks of the management and harvest deferral zones pull from a shared set of candidate patches (nodes) $J$, but the selected patches can only be associated with either the deferral or management zone, except auxiliary Node 0 that is used to inject flow into the selected networks (Fig. 3c in the main text).

The zoning problem selects the connected subnetworks in the harvest deferral and management zones to maximize the amount of connected habitat in the deferral zone, subject to the target area proportion designated for harvest deferral, $\delta$, $\delta \in [0;1]$, i.e.,

$\text{(A1)} \quad \text{max } f_{1} \sum_{u \in U} \sum_{j \in J} \{w_{ju} \beta_{ju}\} \quad \text{subject to } j \in J, u \in U$

$\text{(A2.1)} \quad \sum_{k \in Q_{j}} y_{jku} - \sum_{k \in Q_{j}} y_{jku} = \sum_{k \in Q_{j}} w_{jku} \quad \forall \ j \in J, u \in U$

$\text{(A2.2)} \quad y_{jku} \leq M w_{jku} \quad \forall \ j \in J, k \in Q_{j}, u \in U$

$\text{(A2.3)} \quad w_{jku} \leq y_{jku} \quad \forall \ j \in J, k \in Q_{j}, u \in U$

$\text{(A2.4)} \quad \sum_{k \in Q_{j}} w_{jku} \leq 1 \quad \forall \ j \in J, u \in U$

$\text{(A3.1)} \quad \sum_{k \in Q_{j}} z_{jk} - \sum_{k \in Q_{j}} z_{kj} = \sum_{k \in Q_{j}} v_{jku} \quad \forall \ j \in J, u \in U$

$\text{(A3.2)} \quad z_{jku} \leq M v_{jku} \quad \forall \ j \in J, k \in Q_{j}, u \in U$

$\text{(A3.3)} \quad v_{jku} \geq z_{jku} \quad \forall \ j \in J, k \in Q_{j}, u \in U$

$\text{(A3.4)} \quad \sum_{k \in Q_{j}} v_{jku} \leq 1 \quad \forall \ j \in J, u \in U$

$\text{(A4)} \quad p_{1u} \geq \sum_{j \in J} y_{j} - 1 \quad \forall \ u \in U$

$\text{(A5)} \quad p_{2u} \geq \sum_{j \in J} y_{j} - \theta \quad \forall \ u \in U$

$\text{(A6)} \quad \sum_{k \in Q_{j}} v_{jku} + \sum_{k \in Q_{j}} w_{jku} = 1 \quad \forall \ j \in J, u \in U$

$\text{(A7)} \quad \sum_{k \in Q_{j}} v_{jku} \geq \Psi_{j} \quad \forall \ u \in U, j \in J$

$\text{(A8)} \quad \sum_{j \in J} \sum_{k \in Q_{j}} v_{jku} \geq 1 \quad \forall \ u \in U$

$\text{(A9)} \quad 0.95 \sum_{j \in J} \sum_{k \in Q_{j}} (w_{jku} \alpha_{j}) \leq \delta \sum_{j \in J} \alpha_{j} \quad \forall \ u \in U$

Objective (A1) maximizes the total amount of connected habitat in the area minus the penalties $p_{1u}$ and $p_{2u}$. Penalty $p_{1u}$ denotes the number of connections to Node 0 above one in the deferral zone in period $u$, which defines the maximum number of separate connected subnetworks. Penalty $p_{2u}$ defines the number of connections to Node 0 in the management zone above $\theta$ in period $u$, where $\theta$ defines the number of patches with access points where roads enter the target area. This penalty limits the maximum number of disjoint clusters of connected nodes in the management zone. Coefficients $f_{1}$ and $f_{2}$ adjust the relative weights of the objective and penalties and are set high to force the penalty equations to work under normal circumstances as hard constraints. The penalty formulation keeps the problem feasible when a complex landscape configuration does not allow delineating...
either the management or the harvest deferral zone as a single contiguous area.

Constraints (A2.1 and A3.1) describe the flow balance through patch $j$ in the subnetworks comprising the management and harvest deferral zones, respectively, in period $u$. Set $Q_j$ denotes adjacent patches $k$ and an auxiliary Node 0 that are connected to patch $j$ and can transmit flow to $j$, and set $Q_j^-$ denotes adjacent patches $k$ that are connected to patch $j$ and can receive flow from $j$. Constraints (A2.2 and A2.3) and (A3.2 and A3.3) ensure agreement between the amounts of flow through arc $kj$ in the subnetworks in the management and deferral zones and the corresponding arc selection variables $w_{2u}j$ and $v_{3u}$ in period $u$. Constraints (A2.4 and A3.4) aim to track the flow between the connected patches $j$ and ensure that the flow to a patch $j$ in the management or deferral zone comes from at most one source.

Constraints (A4 and A5) define penalties $p_{1u}$ and $p_{2u}$. Constraint (A6) specifies that patch $j$ can only be in the harvest deferral or management zone in period $u$ but not in both. Constraint (A7) ensures that the management zone always includes patches with permanent roads. A binary parameter $\Psi_j$ defines patches $j$ with permanent roads ($\Psi_j = 1$ and $\Psi_j = 0$ otherwise). Constraint (A8) specifies that the management zone includes at least one patch in period $u$ where roads enter the area. This ensures the accessibility of the management zone in period $u$. A binary parameter $\Phi_j$ defines patches with access points to the area ($\Phi_j = 1$ and $\Phi_j = 0$ otherwise). Constraint (A9) sets the target proportion of the area with deferred harvest in period $u$ to $[0.95; \delta]$, where $\alpha_j$ is the area of patch $j$.

2. Forest access roads construction model

Harvesting remote areas requires building access roads. We track expansion of the forest road network over timespan $T$ with a network flow model that finds a growing subgraph of roads connected to the sites for planning periods $t = 1, \ldots, |T|$, where $|T|$ is a cardinality of set $T$. To reduce combinatorial complexity, we applied the road construction problem at the coarse scale of the network of patches $j$ we used in the zoning problem (A1–A9). The forest area includes a set of harvestable sites $n$ and is also divided into a set of coarse-scale patches $j$. The area of patch $j$ in network $J$ is larger than the area of a harvest site $n$, so we needed a binary parameter $\Lambda_nj$ to indicate whether site $n$ is located in patch $j$ ($\Lambda_nj = 1$ and $\Lambda_nj = 0$ otherwise) (see Figs. 3c and 3d in the main text).

For each planning period $t$, we find a connected subgraph of roads that starts from patches $j$ with roads built in previous periods $1, \ldots, t − 1$ and ends in patches with harvest in period $t$. Analogous to the habitat connectivity problem (A1–A9), an auxiliary Node 0 injects the flow into the network of patches with roads. Node 0 is connected to all patches with roads where the construction of new roads could potentially start. The flow from Node 0 through patches with roads ensures the connectivity of the road network. A binary variable $h_{kjt}$ indicates the selection of flow through arc $kj$ between patches $k$ and $j$, which denotes road construction from $k$ to $j$ in period $t$. A non-negative variable $q_{kjt}$ defines the amount of flow between patches $k$ and $j$ when a road is built from $k$ to $j$ in period $t$ (i.e., $q_{kjt} > 0$ when $h_{kjt} = 1$ and $q_{kjt} = 0$ when $h_{kjt} = 0$). Patches $j$ with incoming flow from other patches or Node 0 form the road network in period $t$. The following constraints control the expansion of the road network over timespan $T$:

(A19.1) $\sum_{k \in Q_j} q_{kjt} - \sum_{k \in Q_j^-} q_{kjt} = \sum_{k \in Q_j} h_{kjt} \quad \forall \ j \in J, t \in T$

(A19.2) $q_{kjt} \leq Mh_{kjt} \quad \forall \ j \in J, k \in Q_j, t \in T$

(A19.3) $h_{kjt} \leq q_{kjt} \quad \forall \ j \in J, k \in Q_j, t \in T$

(A19.4) $\sum_{k \in Q_j} h_{kjt} \leq 1 \quad \forall \ j \in J, t \in T$

(A20) $h_{0jt} \leq \Gamma_j \quad \forall \ j \in J$

(A21) $h_{kjt} \leq \Gamma_j + \sum_{r \in \{1, \ldots, t - 1\}} \sum_{k \in Q_j} h_{kjt}^r \quad \forall \ t \in \{2; |T|\}, t' \in T, j \in J$

(A22) $h_{kjt} \leq 2 - \Gamma_j \Gamma_k \quad \forall \ j, k \in J_{roads}, t \in T$

(A23) $\sum_{k \in Q_j} \left[ \sum_{k \in Q_j} h_{kjt} \right] \geq \frac{1}{M} \sum_{n \in N} \left( \Lambda_n \sum_{i \in I} \left( \kappa_{nX_{i,j}} \right) \right) \quad \forall \ t, t' \in T, j, j' \notin J_{roads}$

(A24) $p_{3t} \geq \sum_{j \in J} \sum_{k \in Q_j} \left( h_{kjt} \right) - \tau \quad \forall \ t \in T$

(A25) $\sum_{k \in Q_j} h_{kjt} \leq \sum_{u \in U} \left( \sum_{u \in U} \left( \sum_{k \in Q_j} \left( \sum_{i \in I} \left( \kappa_{uX_{i,j}} \right) \right) \right) \right) \quad \forall \ j \in J, t \in T$

(A26) $1 - \sum_{k \in Q_j} \left( \sum_{k \in Q_j} \left( \sum_{u \in U} \left( \sum_{i \in I} \left( \kappa_{uX_{i,j}} \right) \right) \right) \right) \geq \frac{1}{T} \sum_{t \in T} \left( \sum_{k \in Q_j} \left( \sum_{k \in Q_j} \left( \sum_{u \in U} \left( \sum_{i \in I} \left( \kappa_{uX_{i,j}} \right) \right) \right) \right) \right) \quad \forall \ j \in J, t \in U$

(A27) $h_{kjt} \geq \frac{1}{M} \sum_{n \in N} \left( \Lambda_n \sum_{i \in I} \left( \kappa_{nX_{i,j}} \right) \right) \quad \forall \ j \in J, j' \notin J_{roads}, t \in T$

For convenience, the numbering of equations follows the numbering in the main text. Constraints (A19.1–A19.4) enforce the connectivity of the road network and work analogously to constraints (A2.1–A2.4) in the habitat connectivity problem. Constraint (A20) restricts the selection of arcs $0j$ connecting Node 0 to patches $j$ with pre-existing roads in period $t = 1$. A binary parameter $\Gamma_j$ defines patches with pre-existing roads ($\Gamma_j = 1$ and $\Gamma_j = 0$ otherwise). Constraint (A21) restricts the flow from Node 0 in periods $t = 2, \ldots, |T|$ to patches with roads either pre-existing or built in the previous periods $1, \ldots, t − 1$. Subscript $t$ denotes time periods $t = 1, \ldots, t − 1, t \in T$. Constraints (A20 and A21) ensure that

Forest units (as defined in the provincial forest management plan): BfMx1, balsam fir dominant conifer; BwDom, birch dominant; ConMx, conifer mix; HrDom, hardwood dominant; HrdMw, hardwood mix; OcLow, other conifer lowland; PjDom, jack pine dominant; PjMx1, jack pine mix; PoDom, poplar dominant; PrwMx, red and white pine mix; SbDom, black spruce; SbLow, black spruce lowland; SbMx1, black spruce conifer dominant mix. Rows: pre-transition forest type, columns: post-transition forest type.

Road construction between patches k and j in period t can only proceed from patches that had roads prior to period t. Constraint (A22) prevents road construction between patches that are already connected by pre-existing roads in period t = 1.

Constraint (A23) implies that harvesting sites n in period t in patch j that is outside of the pre-existing road network (i.e., with G_j = 0) is only possible if the road network is extended to j during periods 1,..., t. A binary parameter indicates that site n is harvested in period t in prescription i (i.e., \( \chi_{nit} = 1 \) when \( \gamma_{nit} + \gamma_{2nit} > 0 \) and \( \chi_{nit} = 0 \) when \( \gamma_{nit} + \gamma_{2nit} = 0 \)). Subscript t denotes time periods 1,..., T.

Constraint (A24) defines penalty \( p_{3t} \) for each period t as equal to the total number of patches j with roads built above the maximum limit r. The r value is based on the historical extent of road construction activities in the area. Constraint (A25) prevents road construction to a patch j if j is in the harvest deferral zone in period t. Note that a single period u includes several harvest planning periods t. A binary parameter \( \Xi_{ut} \) indicates that harvest period t occurs within a planning period u in the zoning problem (A1–A9) (\( \Xi_{ut} = 1 \) and \( \Xi_{ut} = 0 \) otherwise). Constraint (A26) ensures that patch j is assigned to the management zone in period u if roads are built in j during the period u. Constraint (A27) defines a binary decision variable \( h_{jt} \) that indicates harvest in patch j in period t and is used to track the road maintenance cost in patch j if harvest occurs in j in period t.

APPENDIX B. Generating a set of harvest prescriptions

The harvest scheduling model required generating a set of prescriptions \( I \), where each prescription defines a possible sequence of harvest events in site \( n \) over a planning horizon of \( T \) periods, including a scenario without harvest. We enumerated all possible management prescriptions that can be assigned to forest site \( n \) by a set of binary vectors of length \( T \), \( \{1,0,\ldots,0\};(0,1,\ldots,0)\;\ldots \). The elements of each vector denote the harvest or other management actions undertaken in planning period \( t \), \( t = 1, \ldots, T \). For each prescription \( i, i \in I \), we calculated the vectors of harvest volumes \( V_{nit} \), the volumes for softwood and hardwood species, \( V_{1nit} \) and \( V_{2nit} \), the post-harvest regeneration costs \( c_{nit} \), the amounts of caribou habitat \( h_{nit} \), and a binary parameter \( W_{nit} \) indicating that site \( n \) is harvested in period \( t \) in prescription \( i \). To simplify the formulation of harvest sustainability constraints, we calculated the areas of mature and old-growth stands for each forest type \( g \), \( \lambda_{g} \) and \( \xi_{g} \), and the areas of young stands, \( \zeta_{nit} \), in site \( n \) in prescription \( i \) in period \( t \). For each site \( n \) and prescription \( i \), we also estimated the forest stand age at the end of the planning horizon \( T \), \( \varepsilon_{nit} \), and the net cash flow from harvest minus harvest, hauling and post-harvest regeneration costs, \( R_{nit} \).

We used Ontario’s Forest Resource Inventory (FRI) database (OMNRF 2020) to depict the spatial locations of sites \( n \) representing potential candidates for harvest. The FRI provided initial tree species composition and stand age at \( t = 1 \). Each forest polygon in the FRI database provides tree species information at the level of “forest units”, i.e., common tree species assemblages that are delineated from aerial photographs for practical forest management (Table A1). For each forest unit, the forest management plan (FMP) for our target area, Wabadowgang Noopming Forest (NorthWinds 2021), provided a

</table>

normal yield curve, which we used to estimate the volumes of harvested timber in site \( n \) as a function of stand age in period \( t \). When calculating the harvested timber volume in prescriptions \( i \), we adjusted the forest area in site \( n \) by the projected annual forest area losses due to fire disturbances using wildfire regime zones from Boulanger et al. (2014).

To estimate the future forest composition and harvest volumes in prescriptions \( i \), we tracked two general types of forest succession over time. Aging succession depicted temporal changes in tree species composition without stand-replacing disturbances as forest stands change from early-successional to late-successional types. Based on the FMP and consultations with NorthWinds staff, we set, for each forest unit, the threshold age when forest composition in site \( n \) changes to a late-successional forest type (Table A1). A matrix of transition rates to late-successional forest types (Table A2) is applied when forest stands reach a threshold age.

The second type of forest succession depicted forest composition changes after clear cut harvest. Based on the FMP (NorthWinds 2021), two sets of succession rules were applied to track post-harvest forest changes in naturally regenerated stands and after replanting (Tables A3 and A4).

Using these succession rules, we generated two sets of prescriptions with natural regeneration and replanting after harvest for the same set of harvest schedules. Each set of prescriptions used a unique post-harvest succession matrix and a corresponding set of post-harvest regeneration costs (Table A1) and normal yield curves. Since natural regeneration and replanting options are characterized by different cost and timber yields, these prescription sets also have different net cash flow values \( R_{nit} \) and vectors of harvested volumes \( V_{nit} \) and \( V_{2nit} \).

Our optimization model did not use individual forest units but instead tracked the forest age structure at the level of four general forest types (set \( G \), see Table 3 in the main text). The Fir group included conifer stands dominated by balsam fir; the Lowland conifer group included black spruce and other conifer-dominated stands in poorly drained sites; the Upland conifer group included stands dominated by conifer species in other topographic positions; and the Hardwood group included stands dominated by deciduous species. For each site \( n \), we generated the areas occupied by each forest group \( g \) that reached mature and old-growth age in prescription \( i \) in period \( t \), \( \chi_{gnt} \) and \( \xi_{gnt} \). For each forest unit, Table A1 shows the forest age when forest stands reach old-growth status.

We estimated the amount of caribou habitat in site \( n \) in period \( t \) in prescription \( i \) using a boreal caribou habitat model for Ontario’s Northwest Region (Elkie et al. 2018) (Table A5). A score of 1.0 was assigned for each habitat type (such as winter useable, winter preferred, and refuge habitat) if present in site \( n \) in period \( t \). A forest site can, depending on its cover category and age class, have a score between 0 and 3 (i.e., 1 for refuge, +1 for useable, +1 for preferred habitat). The total habitat amount \( b_{nit} \) was calculated as the sum of these scores multiplied by the site area. When forest patches included a mix of different forest types, the total habitat value was estimated as a weighted average of scores for individual cover types and their corresponding areas. We assumed that forest stands regain suitable habitat status in 40 years after harvest. The total habitat amount in patch \( j \), \( B_{jnt} \), was calculated as the sum of habitat amounts \( b_{nit} \) in site \( n \) located in patch \( j \), \( n \in N_j \), over periods \( t \) within a timespan \( u, t \in u \).
